Attention to the detail of the child’s nutritional intake is an important aspect of assessment, which may require attention as part of treatment. Aside from the negative impact on growth and physical functioning, inadequate nutrition may be associated with increased irritability and decreased interest in and energy for nonessential activities, such as play (Stallings et al. 1993), which can hinder development. Significant developmental progress has been shown to accompany improved nutritional status (Sanders et al. 1990).

The most common nutritional interventions focus on addressing the micronutrient content of the diet, plus the provision of structured routines and schedules to promote the development of hunger and satiety. For example, in cases where children are progressing from enteral to oral feeding, stability or increase in weight and height can allow for the volume of tube feed to be reduced, which can create a window of appetite and increase the tube-fed child’s interest in oral feeding. However, research suggests this strategy alone is significantly less effective in moving children on to full oral feeding, than when combined with behavioral interventions—see below (Benoit et al. 2000).

Children who have had feeding problems since infancy are unlikely to have the necessary oral motor skills to eat food that would be regarded as suitable for their chronological age. Normally developing children tend to progress through a series of increasingly complex textures during the development of their feeding skills. It is likely that children need to have experience of processing food of one consistency in order to develop the skills required to move onto the next (Morris and Klein 2000). Skill acquisition is an important component of treating feeding disorders (Babbitt et al. 1994). Food should be introduced according to the
child’s ability, experience, and developmental level, rather than their age in order not to compound a preexisting feeding disorder. (Clinical Vignette 3). When inappropriate textures have been introduced too early, the whole process of weaning through stages needs to be reestablished.

A number of children present with “pouching” or “packing,” which is the holding of food in the mouth for lengthy periods. In some children this is related to poor skill acquisition and an inability to manage certain textures. Patel et al. (2005) have shown that offering less textured food can help to reduce this behavior and promote weight gain. In other children, packing or pouching may result from avoidance behavior often arising in the context of a history of reflux or vomiting. In such instances progress may be made through desensitization, graded exposure, and positive reinforcement (see below).

**Psychosocial Treatments**

Psychosocial interventions can be targeted at the child, the caregiver(s), the interaction between child and caregiver, and/or the interaction with the child’s family and wider social and educational system (Davies et al. 2006).

**Individual**

Behavioral interventions, often based on reinforcement contingencies, have been used with reported success by a number of authors. Cooper et al. (1995) describe the successful treatment of four young children with severe feeding difficulties, using individually tailored multicomponent behavioral treatment packages. Techniques used include escape extinction (where the reinforcer to a response is removed in order to decrease the occurrence of this response), contingent attention (praise), contingent reward, noncontingent access to toys and social interaction as distracters during mealtimes, presentation of choice, and warm-up procedures. These authors report that escape extinction was shown to be a necessary treatment component in each case. Benoit et al. (2000) give an example of this technique: the removal of a spoon after gagging or refusal reinforces gagging or refusal as a response to food. Nonremoval of or reoffering the spoon is an extinction procedure designed to alter the gagging and refusal response. However, the 1995 Cooper paper included only four children and extinction as a technique is one that many caregivers and clinicians find difficult to deliver. Other behavioral treatments used in feeding disorders include the Premack principle, time-out plus reinforcement, and negative reinforcement. (The basis of the Premack principle is that a reliably occurring behavior in the child—such as watching a favorite children’s program—can be used as a reinforcer for a less reliably occurring behavior, for example, self-feeding a yogurt; in other words, the child is rewarded for eating the yogurt through watching the TV program; O’Brien et al. 1991.) In children who are progressing from tube feeding to oral feeding, behavioral therapy can focus on reducing fear of swallowing (Benoit et al. 2000).

**Interaction between Caregiver and Child**

Research suggests that parents of feeding-disordered children are more negative and coercive in their feeding practices and engage in higher levels of aversive instruction giving, aversive prompting, and negative eating-related comments (Sanders et al. 1993). For this reason intervention is needed to improve the interaction between parent and child to facilitate a more positive feeding environment.

A significant part of successfully treating many children with feeding disorders is the provision of guidance, support, and reassurance to parents and caregivers. Parent training is considered to be a key aspect of treatment (e.g., Babbitt et al. 1994). Advice can be provided on the use of structured mealtime and snack routines, the mealtime
appropriate development of skills (see Vignette 4). A number of parents may feel guilty about the distress the child has experienced. Treatment intervention will need to include a focus on this aspect of the presentation in order to facilitate an emphasis on fun.

At 3 years of age, Alan was seen for treatment at a behavioral feeding clinic. Graded exposure was used to treat Alan’s food aversion, using a puppet called “Bert.” Initially, Alan was asked, along with the puppet, to sniff different food and nonfood items. With the help of the puppet Alan talked about what smells he liked and smells he did not like. He then played a game where all the smells were placed in black jars and, while blindfolded, he and Bert had to guess which smell was which, receiving a sticker for each correct answer. This task was designed to be attainable and Alan experienced success in this task and became used to doing what was asked of him.

Alan then moved onto touching foods. Along with “Bert” he did painting with food, progressing to finger painting and hand painting and finally moving onto nose prints. There was no expectation to taste any food at this stage and Alan learned to have fun with food and to comply with requests. Each task was very attainable and built slightly on the previous task. Alan did not experience failure in his tasks, which were framed as “work” but also had an emphasis on fun.

Alan then moved on to tiny tastes of food. He was exposed to several different flavors and he picked his favorite, along with “Bert” who also tasted the food and picked his favorite. Both “Bert” and Alan received stickers for each taste.

From there Alan progressed to having a whole spoon of his favorite taste. He was given a sticker for each spoon he swallowed, a medium-sized “gift” for half a yogurt and a large-sized “gift” for a whole yogurt. Over a period of six sessions Alan progressed from sniffling foods to eating full yogurts and the rewards were reduced as success and expectations increased.

Meanwhile, work was also done with Alan’s mother, who due to his prematurity and his poor early health felt very guilty and found it very difficult to set firm boundaries. Work was done with Alan’s mother to work through these feelings at each session and to ensure that she would continue to maintain Alan’s progress between sessions with firm boundaries, expectations, and goals.
gastroesophageal reflux, or vomiting due to other medical causes, and in older individuals must not be better explained by another disorder (anorexia nervosa or bulimia nervosa).

Of interest to note is that in the ICD-10 classification of mental and behavioral disorders, unlike in DSM-IV-TR, rumination disorder is not identified as a separate diagnostic category (World Health Organization 1993). Instead, rumination and regurgitation are included as symptoms under the diagnosis of Feeding Disorder of Infancy and Childhood (F98.2). It is also important to note that infant regurgitation and infant rumination syndrome have also been proposed as being two separate disorders within the classification system for childhood functional gastrointestinal disorders proposed by Rasquin-Weber et al. 1999, also known as Rome II. In this classification scheme, the subgroup of vomiting disorders consists of infant regurgitation, infant rumination syndrome, and cyclical vomiting syndrome. Diagnostic criteria for infant rumination differ from those for DSM-IV-TR Rumination Disorder in a number of respects: there is a requirement for the behavior to have been present for 3 months rather than 1; it is not specified that there should have been a preceding period of normal functioning; there is a relatively narrow age at onset specified (3–8 months) unless all other diagnostic requirements are met (i.e., it can, in some circumstances, be diagnosed in infants with onset over 8 months as long as all other criteria are met) and attention is drawn to a lack of distress in the infant, poor interactions with others, and the behavior not occurring during sleep. This classification system was subsequently updated and revised (Rasquin et al. 2006) to provide Rome III criteria for childhood functional gastrointestinal disorders. Infant rumination syndrome remained unchanged but criteria were added for adolescent rumination syndrome to take account of the observation that rumination occurs across the age range. A number of authors use the term “rumination syndrome” in relation to older children, adolescents, and adults (e.g., Chial et al. 2003, Malcolm et al. 1997). As with the term “feeding disorder,” there is variation in the use of the terms “rumination,” “rumination disorder,” and “rumination syndrome.”

Assessment
A major consequence in infants and young children with rumination disorder is the tendency to weight loss, with the related risk of malnutrition and susceptibility to infection, disease, and even death (Franco et al. 1993). Growth and physical development may be impaired if basic nutritional requirements are not met. Other complications of rumination include halitosis, dental damage, electrolyte abnormalities, and abdominal pain. Some authors have described a typical posture adopted by infants with rumination disorder, which is characterized by an arched back, backward tilt to the head, and contraction of abdominal muscles, representing attempts to regurgitate part digested food, while others describe the regurgitation as “effortless” (Nicholls 2004).

Assessment will typically include a medical and developmental history and present state evaluation including the following:

- feeding history (must have been normal prior to rumination);
- onset and development of rumination behavior, with identification of any triggers for behavior;
- medical history of gastrointestinal problems and other medical conditions;
- present weight, height, and calculation of body mass index centile or Z-score;
- presence of concurrent medical complications related to vomiting and regurgitation, for example, dehydration, aspiration pneumonia, and stomach ulcer;
- blood tests to check electrolytes and nutritional disturbances and deficiencies; and
- presence of concurrent or associated psychosocial disturbances.

Assessment also usefully includes direct observation both during and after feeding. This enables observation of the swallow, plus identification of the typical posture mentioned above.

Epidemiology
As mentioned above, there is considerable variability in the use of terms in relation to rumination disorder; thus, it is very difficult to make clear statements about incidence and prevalence. A number of authors use terms such as “uncommon” or “relatively rare” (e.g., Franco et al., 1993, in relation to rumination in infancy). Rumination disorder typically develops within the first year of life, and many children grow out of it spontaneously. Where it occurs in older individuals it may be misdiagnosed, or in the case of adolescents and adults, not result in a clinical referral, sometimes due to embarrassment on the part of the sufferer. The symptom of rumination is nonspecific and may result in an individual being referred to one of a number of different types of clinic (e.g., gastroenterology, behavioral feeding, etc.), and thus again, consistent figures are hard to come by. Consequently, it is very difficult to know how many people of different ages are affected. Olden 2001 reports that “rumination” occurs in 6–10% of developmentally disabled children living in institutions.

Primary prevention of rumination disorder is not possible. Secondary prevention in the form of early behavioral intervention at initial observation of regurgitating and rechewing behavior may well help to minimize its establishment, thereby reducing the risk of adverse medical complications.

Course
Rumination disorder tends to run a different course depending on the type of patient it occurs in. In most infants, it tends to resolve over time, and the child eventually returns to normal feeding. However, in a few it can be associated with choking, serious medical complications, and can result in death. In older children, particularly those with pervasive developmental delay and developmental disability, it can be a more refractory problem, often developing into a longstanding habitual behavior that may prove very hard to address. In older patients who develop rumination disorder in the context of anxiety, or other psychiatric symptoms, its course will often be associated with the course of the comorbid psychiatric presentation.

Differential Diagnosis
Alternative causes of regurgitation or vomiting will need to be ruled out. The most obvious are gastrointestinal conditions
and disorders, such as gastroesophageal reflux, pyloric stenosis, or gastrointestinal infections. Further investigation and examination by a physician, involving laboratory tests as appropriate, may be required to rule out primary medical causes. Many infants experience periods of vomiting or possetting, which can be distinguished from rumination disorder by the absence of the characteristic preparatory movements and apparent pleasure derived from the behavior. Regurgitating and spitting out food has also been well described as a symptom of an eating disorder in older individuals (Birmingham and Firoz 2006, Eckern et al. 1999). Anorexia nervosa and bulimia nervosa will therefore need to be ruled out.

Differences in Developmental, Gender, and Cultural Presentations
Within the current DSM system, we have seen that rumination disorder can occur across the age range. In infants it has been reported as occurring at a higher rate in boys than in girls (Mayes et al. 1988). In older individuals it has been found to be more prominent in females than males (Chial et al. 2003). It occurs in individuals of normal intelligence and in those with mental retardation, with apparent differences in function (see next section).

Etiology and Pathophysiology
A range of etiological mechanisms have been proposed in understanding the development of rumination disorder. The main etiological factors include the following:

- stress and anxiety combined with inadequate communication strategies or coping mechanisms may trigger the disorder, and
- need for stimulation.

In infants, anxiety and stress have been postulated as deriving from problematic aspects of the mother-infant relationship, as well as from physical illness. Rumination has been associated with neglect or failure to establish a close emotional bond with a primary caregiver. The behavior can be understood as a means of self-stimulation, self-soothing, and/or as an expression of distress. The repeated regurgitation and chewing may be a soothing behavior that the child uses to reduce anxiety or gain comfort. In children with pervasive developmental disorder, it may be understood as similar to other repetitive behaviors that the child engages in.

It seems likely that rumination disorder as defined by DSM-IV-TR is a learned behavior, which may or may not have had an underlying medical trigger. In some cases there may have been an early history of reflux or an episode of vomiting or other illness. For the diagnosis to be made, these must no longer be the main cause of the regurgitation. They may however have resulted in increased caregiving, so that an infant might learn to associate vomiting with eliciting positive attention.

Rumination disorder is not in itself currently understood as a disorder with high heritability, although research in this area is lacking. However, it can be associated with ASD and other pervasive developmental disorders, which do have a strong genetic component. It seems most likely that in most cases of rumination disorder in infants and young children, nonshared environmental influences combined with cognitive capacity and temperament might best account for its development.

Treatment

Treatment Goals
Rumination Disorder is characterized by problematic behavior; the usual goal of treatment is to alter that behavior and address any adverse sequelae (e.g., low weight and malnutrition). As with most childhood disorders, treatment planning will require a consideration of features specific to the child and to the child’s environment.

Psychosocial Treatments
Attention is usually paid to both the feeding situation and the interaction during feeding. For example, the infant’s posture during and after feeding is important, and advice may be given to change this. The classic arching of the back can often be remedied by encouraging attention and physical contact after feeding. Greater interaction between mother and child can be helpful both during and after feeding. This can serve to distract the child from the need to self-sooth or self-stimulate, thereby reducing the problem behavior. Particularly in children with rumination disorder in the context of pervasive developmental disorder, reducing distraction and other external forms of stimulation while feeding is taking place can significantly reduce regurgitating behavior. A general emphasis on establishing feeding and mealtimes as calm, nonthreatening, and enjoyable is advised.

Behavioral approaches, in particular, operant conditioning, have been documented as having positive outcomes in infants and young children with rumination disorder. The practice of ignoring undesirable behavior and rewarding desirable behavior with praise and attention is widely used and recommended by many clinicians. However, this is often not effective in situations where the behavior in itself serves a positive function, such as self-soothing or comfort; ignoring it is unlikely to result in diminution of the behavior (see Vignette 5).

Another behavioral modification technique, aversive conditioning, used to be a recommended treatment approach for rumination disorder. Such an intervention consisted of an unpleasant stimulus being delivered contingent on regurgitation, usually in the form of a sour or hot substance being placed on the child’s tongue. This technique raises ethical concerns and its effectiveness proved to be inconsistent (Olden 2001). It is now no longer widely used, with a current clear preference for distraction, environmental changes, and emphasis on promoting interaction and reinforcement of desirable behavior (e.g., Franco et al. 1993). In the case of significant problems in the relationship between the main caregiver(s) and the infant, treatment may be primarily focused on improving the bond between the two. Typically, this will involve encouraging the caregiver to respond appropriately to the infant’s cues, not just around feeding but also in other areas of activity and interaction, thereby helping the infant to learn to communicate. This may in practice involve working with one or both parents. In some instances, caregivers present to the clinician with strong negative feelings toward the child. They may have been told that there is no obvious medical cause for the child’s behavior, which in some cases seems to contribute to a sense of frustration and induces a sense of powerlessness. Such negative feelings will need to be addressed, as otherwise they may serve to perpetuate the behavior.
Somatic Treatments
Medication is not generally recommended as treatment for DSM-IV-TR Rumination Disorder in infants and young children.

Pica

Diagnosis

Definition and Diagnostic Features
Pica is the diagnostic term used to denote individuals with a specific form of eating disturbance characterized by the ingestion of nonfoodstuffs, which must have persisted for at least 1 month prior to diagnosis. The term “pica” is usually held to come from the Latin word for magpie (picus), referring to the indiscriminate feeding habits of these birds. Substances ingested by individuals with pica may include chalk, soil, plaster, clay, paint, paper, cloth, sand, hair, plastic, coal, insects, wood, pebbles, and animal feces—in effect anything that can be put into the mouth. Some clinicians also use the term to include the eating of foodstuffs in a raw or unprepared form, such as flour or raw potatoes, although technically such substances are not “nonnutritive,” as specified in the diagnostic criteria (see below).

In their historical review, Parry-Jones and Parry-Jones 1992 conclude that there is no evidence to suggest that at any time before the 20th century was pica regarded as a separate disorder. Drawing from documents from the 16th century when the term “pica” was first used, they conclude that it was for centuries regarded as a symptom of other disorders. However, in both of the current main classification systems, DSM-IV-TR (APA 2000) and ICD-10 (WHO 1993), pica does appear as a separately diagnosable disorder.

Using the DSM-IV-TR classification scheme, pica can be diagnosed in individuals of all ages. However, ICD-10 refers only to “pica of infancy and childhood.” A further difference between the two classification systems is that in DSM-IV-TR, pica may be diagnosed in the context of another mental disorder (e.g., mental retardation, pervasive developmental disorder, and schizophrenia), whereas in ICD-10 it is specified that the child should have no other mental disorder with the exception of mental retardation (World Health Organization 1993). Pica is also well known to occur in pregnancy and in individuals with nutritional deficiencies. In this chapter pica will be discussed specifically in relation to young children as an emotional/behavioral disorder. Within this age group, children with pervasive developmental disorder and mental retardation are most likely to display this behavior. When occurring in association with these disorders, the pica must be considered sufficiently severe to warrant clinical attention in its own right in order to justify a diagnosis. Pica can also occur in children with no other mental disorder.

It is well recognized that children go through a “mouthing” stage as part of normal development and that most normally developing children ingest some nonnutritive materials during this period. For this reason, ICD-10

**Clinical Vignette 5**

**Rumination Disorder in an 11-Month-Old Girl**

Cara was seen in the Feeding Clinic at the age of 11 months. She had been bottle fed from birth and had started weaning at 4 months onto purées. Initially, she had fed with no problems and her growth and weight had been satisfactory. At 6 months she had moved onto jars of baby food and then to finger foods, but still had not made the transition to taking fluids from a beaker or cup. Regurgitation was reported to have started at around the age of 6–7 months and by the time of presentation, Cara was regurgitating and rechewing throughout the day. She was also reported to have vomit in her bed some mornings. Cara’s weight and behavior were a cause for significant concern.

Cara was the fourth child of Louise, 25. Louise had her first child at the age of 17, and had her four children by two different partners, both of whom no longer lived with the family. Cara’s father had left a few months previously after a period of frequent arguing and disagreements. Louise now received some support from her parents and worked part-time. The team’s understanding of the context for the problem was that Cara’s family situation was very unsettled. Louise had multiple demands on her time and while she had bottle fed and then weaned Cara initially, she had passed over the task of feeding Cara to others whenever possible, including her two older children (age 7 and 5). Louise had struggled with depression and stress and had found it difficult to establish a close bond with Cara. She was house proud and wanted her children to look clean and well cared for. She spent many hours cleaning, washing, and tidying, and little time with Cara. Whereas she had spent more time with her until around the age of 6 months, this had gradually reduced. Cara’s regurgitation was understood in the context of an increasingly distant relationship with her mother, a chaotic feeding regime, and relatively long periods of time being left without direct stimulation.

In Cara’s case, regurgitation and rechewing appeared to be self-soothing, comforting behaviors, which she engaged in when she was alone or in her cot. Louise’s exasperation at soiled sheets and clothes was understood as a further tension in their relationship. Cara’s deteriorating physical state contributed to Louise’s depression and feelings of being unable to cope with her. Treatment consisted of encouraging positive interaction around feeding and at other times, seeking out practical sources of support for Louise, and establishing a regular mealtime routine for the whole family. Recommendations to ignore the regurgitation were not made, as this was deemed to be likely to be ineffective given the specific context for Cara’s problem.

---

**DSM-IV-TR Criteria**

**Pica**

A. Persistent eating of nonnutritive substances for a period of at least 1 month.
B. The eating of nonnutritive substances is inappropriate to the developmental level.
C. The eating behavior is not part of a culturally sanctioned practice.
D. If the eating behavior occurs exclusively during the course of another mental disorder (e.g., mental retardation, pervasive developmental disorder, schizophrenia), it is sufficiently severe to warrant independent clinical attention.

requires a minimum chronological or mental age for diagnosis of 2 years, while DSM-IV-TR states that the ingestion of nonfoodstuffs is inappropriate to the developmental level of the individual.

**Assessment**

A comprehensive review of the child’s nutritional intake is recommended in all cases of childhood pica. This will include attending to the specifics of the problematic eating behavior, including possible underlying physical causes for it, the presence of any complications arising from the ingestion of nonnutritive substances, the child’s psychosocial environment, and the presence of conditions such as mental retardation or pervasive developmental disorder.

Eating nonnutritive substances can be the result of nutritional deficiencies, in particular, iron deficiency. In order to rule this out as primary cause, a nutritional assessment of daily diet should be considered. However, it is possible for lead poisoning, which may result from pica, to result in iron deficiency, in which case it can be hard to disentangle whether the deficiency is cause or effect. In the same way, the ingestion of poisonous substances may contribute to brain damage and learning disability in the child, as well as developmental disabilities increasing the risk of ingesting nonnutritive substances. A further reason for carrying out a dietetic review is because pica may affect appetite, which in turn may result in reduced consumption of normal food, leading to nutritional deficiency.

The effects of eating nonfoodstuffs can range from being relatively harmless to potentially fatal. An important aspect of assessment is therefore to determine exactly what is being eaten and to assess quantities eaten. The most common harmful outcomes of pica in children include lead poisoning, other accidental poisoning, parasitic infestation, infections, gastrointestinal obstruction, the formation of bezoars, and/or laceration. The clinician will ideally need to match the substance ingested with the presence of any symptoms in the child to determine appropriate medical treatment. However, in young children, information about ingested substances will often depend on parental or caregiver report, and the child’s behavior may not have been directly observed. In some cases parents are not aware of the nature and extent of the child’s behavior. Clearly, the severity of the consequences will vary considerably, depending on the substance in question. Where this is not known, delay in diagnosis and appropriate management may occur.

The presence of abdominal pain and other gastrointestinal symptoms, such as constipation, diarrhea, vomiting, loss of appetite, abdominal distension, and nausea, should always be assessed, due to the possibility of blockage, damage, infection, or infestation. In relation to specific medical investigations, blood lead screening, imaging studies, and endoscopy may be indicated.

The third component of assessment for pica (besides the nature of the behavior and any possible complications) is to obtain a good understanding of the child’s psychosocial environment. Some children presenting with pica may be unsupervised or understimulated for long periods, and in some children, the development of secure attachment relationships may have been disrupted. A narrow focus on symptoms and complications alone would miss these aspects of presentation.

Finally, assessment for the presence of mental retardation or pervasive developmental disorder is an important part of attempting to understand the function and context for the behavior and will influence approaches to treatment.

**Epidemiology**

As mentioned previously, in children, pica most commonly occurs in those with pervasive developmental disorder and mental retardation. There are some prevalence figures for pica in institutionalized adults (e.g., 9.2% of 607 such adults—McAlpine and Singh 1986), but rates overall for infants and young children are difficult to ascertain. Much of the literature is based on case report studies.

**Comorbidity**

The main comorbid presentations of pica are mental retardation and pervasive developmental disorder.

**Course**

As with rumination disorder, pica may be a transient disorder, which remits spontaneously, or may be a more established behavioral problem depending on the type of patient. In children with severe forms of mental retardation or pervasive developmental disorder, the behavior may be left untreated, or if interventions are attempted, difficult to alter and thus persist. The prognosis is additionally varied in relation to those particular substances that are ingested. It can range from being harmless to resulting in death. In general, though, most authors describe pica as most commonly remitting in young children, usually after a period of a few months.

As with rumination disorder, primary prevention of pica is not possible. Observation of the child’s eating habits, supervision of feeding, and appropriate guidance and training regarding what is and what is not suitable to eat may prevent the establishment of significant problems.

**Differential Diagnosis**

Mouthing is a normal developmental stage, usually occurring around the age of 18–24 months, and the accidental ingestion of nonnutritive substances is not uncommon. Pica should be diagnosed only when eating inedible substances persists for 1 month and is inappropriate for the individual’s developmental level.

In cases when consumption of nonnutritive substances occurs during the course of another mental disorder, such as pervasive developmental disorder or Kleine–Levin syndrome, a diagnosis of pica should only occur in instances where the eating of nonnutritive substances is severe enough to require additional and independent treatment.

Korman 1990 describes three cases of children presenting with pica resulting from iron-deficiency anemia. In all of these children the anemia was secondary to malabsorption related to celiac disease. Treatment in these cases consisted of observing a gluten-free diet. In all these children this resulted in a growth spurt plus complete resolution of pica. This author recommends that where pica is persistent and combined with growth delay, celiac disease should be considered even in the absence of gastrointestinal symptoms.
Differences in Developmental, Gender, and Cultural Presentations

Pica occurs across cultures, and in some societies the practice of eating nonfoodstuffs is culturally sanctioned and not considered disordered. For example, in some African countries and in India, the practice of eating soil is not uncommon; indeed, soil may be made available for sale for this purpose. For this reason both DSM-IV-TR and ICD-10 definitions state that the behavior must not be part of a culturally sanctioned practice. Although pica often occurs in people living in poverty (possibly due to nutritional deficiencies), it can be present in individuals from all social groups. In childhood, it occurs in both boys and girls, and in older individuals with mental retardation it is also reported roughly equally across both males and females. In adults without mental retardation and not living in poverty, pica occurs most often in the context of pregnancy. It is relatively rare in adolescent and adult males of normal intelligence, where there is no cultural practice of eating nonfoodstuffs.

Pica is not usually diagnosed below the age of 18 months (24 months if using ICD-10 criteria). It becomes less common with age in individuals of normal intelligence with no developmental disorder.

Eiology and Pathophysiology

Parry-Jones and Parry-Jones 1992 report that over the centuries a variety of causes have been identified for pica, including those remaining closely associated with our current understanding of factors contributing to its development, such as developmental disability, nutritional deficiencies, pregnancy, and emotional deprivation.

As mentioned in the section on assessment, it is often difficult to distinguish the precise cause of pica in any one individual. Mineral deficiencies (e.g., iron, zinc, and calcium) are often cited, but not all children with pica are mineral deficient, and not all substances eaten contain the missing substance. In children with developmental disability, pica may result from a persistent habit of mouthing objects and/or lack of discriminatory ability. Its persistence is usually understood in terms of behavioral learning theory; the behavior is associated with a positive reward (e.g., comfort) and therefore persists. Lack of stimulation, lack of supervision, self-soothing, comfort seeking, and hunger have all been suggested as underlying the development and persistence of the unusual feeding behavior.

Treatment

Treatment Goals

As with other types of feeding problem, the main aims of treatment for pica are twofold: to address the behavior and to manage and treat any adverse consequences. Again, this will in many cases require multidisciplinary input.

Psychosocial Treatments

In terms of addressing the behavior itself a range of behavioral strategies are reported in the literature. As with rumination disorder, the more aversive techniques, such as contingent aversive taste, smell, or sensory stimuli, which were widely used a few decades ago, have become much less common. The more positive behavioral strategies based on positive reinforcement and discrimination training tend to be more widely used. As in so many areas of managing children’s problem behavior, there has been a clear shift away from associating directly aversive consequences (e.g., unpleasant stimuli, punishment, and deprivation), with engaging in the problem behavior, to the encouragement of normal behavior through positive consequences for altering behaviors in that direction.

Addressing the behavior will in most cases also include psychosocial and environmental interventions, such as altering the physical environment to reduce availability of non-nutritive substances, improving supervision, and working on promoting interaction and stimulation. In some children, pica seems to be related to a lack of sensory stimulation, and thus a focus on providing alternative sensory experiences can help to reduce or eliminate the inappropriate feeding behavior.

Finally, educational input may be required for parents and caregivers to alert them to the risks of eating certain substances.

Somatic Treatments

There are no medications specific to the management of eating nonnutritive substances. However, depending on what has been ingested, a range of medications may need to be administered to manage the consequences. As mentioned previously, pica may result in significant levels of malnutrition, including vitamin and mineral deficiencies, which may indicate a need for nutritional supplementation. It is unlikely though that where a nutritional deficit is identified at assessment, nutritional treatment of that deficit alone will be sufficient. Nevertheless, there are some small case studies in the literature that suggest otherwise; for example, Arbiter and Black 1991 describe two children with a diagnosis of pica referred to a child psychiatry clinic. Both these children had undiagnosed iron-deficiency anaemia, which when treated led to resolution of pica.

Special Factors Influencing Treatment

Similar to rumination disorder, where pica occurs in the context of mental retardation or pervasive developmental disorder, it can prove more difficult to alter the behavior. The effectiveness of discrimination training may be limited in such children and reward-based reinforcement approaches less potent. However, environmental manipulation, distraction, stimulation, and interaction are all useful techniques, and with consistent application, pica can be successfully managed.

Acknowledgment

The authors thank Una McCran, Clinical Nurse Specialist with the Feeding Team at Great Ormond Street Hospital, for her invaluable knowledge, experience, and support in the writing of this chapter.

Chapter 47 • Feeding Disorders of Infancy or Early Childhood

It has been more than 100 years since Gilles de la Tourette first described the often complex and puzzling disorder that now bears his name, Gilles de la Tourette syndrome (Tourette’s disorder (TD)). In the past 30 years, efforts to increase awareness of TD (and other tic disorders), improve diagnostic accuracy, decrease stigma, and stimulate research have largely been successful. Research has demonstrated that tic disorders are more common than previously thought, have a genetic etiology, and are often complicated by co-occurring behavioral and emotional problems. Improved understanding of tic disorders and common co-occurring disorders as well as increased availability of efficacious treatments has resulted in the promise of better outcomes and less stigma for individuals with TD.

Despite the opportunity for enhanced outcomes, inadequate dissemination of assessment and treatment advances has left many with TD without access to knowledgeable medical professionals. Modern psychiatrists are ideally suited to integrate research findings into improved diagnostic and treatment approaches. As such, this chapter is intended to close the dissemination gap by reviewing and updating the knowledge base and discussing evidence-based approaches to addressing the complex treatment needs of patients with TD and other tic disorders.

**Diagnosis**

**Phenomenology**

**Tics**

The cardinal features of TD and tic disorders are the presence of motor and/or vocal tics. Tics are defined as sudden, repetitive movements, gestures, sounds, or utterances that typically mimic some fragment of normal behavior. Tics are characterized as simple or complex.

Simple motor tics are usually brief, rapid movements of individual muscle groups (e.g., eye blinking, head shaking, shoulder shrugging, etc.). Complex motor tics are typically slower, rhythmic, and involve multiple muscle groups (e.g., simultaneous eye deviation, dystonic postures, even sequences of simple motor tics). Some complex motor tics appear more purposeful, such as stereotyped crouching and hopping, repetitive touching or rubbing, and, less commonly, obscene gestures (copropraxia).

Simple vocal tics are usually brief staccato-like sounds caused by quick diaphragmatic contractions and resulting forceful movement of air through the nose and mouth. They include sniffing, throat-clearing, grunting, whistling, and animal noises. Complex vocal tics include utterances such as words, phrases, and repeating one’s own words (palilalia) or the words of others (echolalia). Uttering obscene words/phrases (coprolalia) or other socially inappropriate word/phrases is not essential for diagnosis and is uncommon with approximately 10% of TD cases so affected (Robertson 2003).

Tics typically begin in early childhood (5–7 years of age), wax and wane in severity, and change in kind and character over time. Tics are exacerbated by excitement, stressful events and internal tension. Conversely, there is often an attenuation of symptoms during periods of focused, productive activity, deep relaxation and sleep. Tics are involuntary, but they may appear to be volitional as they can be suppressed for brief periods and may appear in reaction to environmental events (e.g., mimicking another’s mannerisms.
or speech). In some individuals, tics are preceded by a thought or physical sensation referred to as a “premonitory urge” (Leckman et al. 1993a). Patients noting premonitory urges often describe a period of persistent “inner tension” prior to the tic and a quiescent period of varying length following the tic. Although reported by a majority of adults with TD, premonitory urges are described by fewer than half of youths with the disorder and may be a function of increasing introspective awareness during adolescence (Banaschewski et al. 2003).

**Diagnostic Criteria for the Tic Disorders**

There are four diagnostic categories included in the tic disorders section of the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000): (1) TD, (2) chronic motor or vocal tic disorder (CTD), (3) transient tic disorder (TTD), and (4) tic disorder not otherwise specified (TD, NOS), which is a residual category for tic disorders not meeting the duration or age criteria of the other categories (see DSM-IV-TR Criteria boxes). Diagnostic decisions are typically based on the presence of motor and/or vocal tics, duration of tic symptoms, age of onset, and absence of contributory medical conditions or medications. Other diagnostic schemas have been developed for research purposes (i.e., genetic and epidemiological studies) and include special diagnostic modifiers. For instance, tic disorders not witnessed by a knowledgeable observer are termed tic disorders by history; the modifiers possible, probable, and definite are also added as estimates of diagnostic confidence of a tic disorder diagnosis in such cases (The Tourette Syndrome Classification Study Group 1993).

**DSM-IV-TR Criteria**

**Tourette’s Disorder**

A. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently. (A tic is a sudden, rapid, recurrent, non-rhythmic, stereotyped motor movement or vocalization.)

B. The tics occur many times a day, (usually in bouts) nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.

C. The onset is before age 18 years.

D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).

**Chronic Motor or Vocal Tic Disorder**

A. Single or multiple motor or vocal tics (i.e., sudden, rapid, recurrent, non-rhythmic, stereotyped motor movements or vocalizations), but not both, have been present at some time during the illness.

B. The tics occur many times a day nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.

C. The onset is before age 18 years.

D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).

E. Criteria have never been met for Tourette’s disorder.

**Transient Tic Disorder**

A. Single or multiple motor and/or vocal tics (i.e., sudden, rapid, recurrent, non-rhythmic, stereotyped motor movements or vocalizations).

B. The tics occur many times a day, nearly every day for at least 4 weeks, but for no longer than 12 consecutive months.

C. The onset is before age 18 years.

D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington’s disease or postviral encephalitis).

E. Criteria have never been met for Tourette’s disorder or chronic motor or vocal tic disorder.

**Single Episode or Recurrent**

**Diagnostic Assessment**

**Clinical Presentation**

Prior to the 1980s, only patients with severe and clinically obvious tics were diagnosed with TD. The majority of these patients were adults who were correctly diagnosed only when their tic symptoms became disabling and when classic symptoms such as coprolalia appeared. Despite experiencing
distress or stigmatization, adults with mild tics may not have pursued evaluation and treatment due to a lack of awareness in the lay and professional communities. Children during this era may not have been identified by their parents or were seen as having other behavioral or psychiatric difficulties by clinicians (i.e., hyperactivity or anxiety). In turn, tic symptoms may have been relabeled as fidgeting or anxious habits and subsumed under other diagnoses.

As medical and public knowledge regarding tic disorders increased, younger children with milder symptoms presented for treatment. Today, the challenge is often not identification of the tic disorder, but rather proper identification of co-occurring psychiatric difficulties, which often are more disabling than tics.

The family's initial concern usually determines the medical specialty first consulted regarding tic symptoms. Children with an affected parent usually present directly to a neurologist or psychiatrist for evaluation. Symptoms-wise parents typically seek evaluation early in the course of their disorder, often before a clear diagnosis can be made or tic-suppressing treatment is necessary. Parents with limited exposure to tic disorders may initially consult their pediatrician, incorrectly consult an eye doctor for blinking, or an allergist for sniffing and throat clearing. More than half of families who ultimately pursue expert consultation learn about tic disorders through the media. Although the media has increased public awareness, many parents who first learn about TD from dramatic cases in the media can be fearful that early tic symptoms lead invariably to a debilitating, lifelong disorder. Tic disorders are also frequently identified during evaluation for other disorders such as attention-deficit/hyperactivity disorder (ADHD). When the TD diagnosis is made as part of an evaluation for other problems, it can be particularly difficult for the family and the patient to cope with the additional and unexpected diagnosis.

Although most cases of TD are identified in childhood, some individuals first seek an assessment as adults. Adults who present for evaluation will likely have a lifelong history of tics, but may not have been severely affected earlier in their lives. They often seek evaluation after their child was diagnosed or following a media story about TD. They may have experienced associated psychosocial stigma, been misdiagnosed, or even subjected to inappropriate treatments. For these adults, the relief provided by formal diagnosis may be attenuated by resentment for incorrect misdiagnoses and related treatment failures or simply the challenge of understanding themselves anew.

### Tic Severity Ratings

The rating of tic severity begins with identifying specific movements and/or sounds as well as associated distress and impairment. A typical starting point is asking patients and their families about the life-time presence of common motor tics proceeding from head to toe through common muscle groups. Questions related to the presence of simple sounds and more complex vocalizations are best completed after assessment of motor tics as vocal tics usually develop later than motor tics. After identifying the types of tics, eliciting information about the number, frequency, forcefulness, intrusiveness, and social impact of tics, as well as the patient's ability to suppress tics provides information about impairment. Premonitory sensations or urges, while not critical to diagnosis, may also impair academic, psychosocial, or occupational functioning. Identifying the characteristic course of tic disorders is also important for diagnostic confidence (i.e., childhood onset with simple motor tics in the face).

Tics associated with greater impairment include exaggerated, disruptive, and/or painful movements, vocalizations that call attention to the patient, tics that are socially unacceptable (i.e., coprolalia, copropraxia, etc.), and those with intrusive premonitory urges. Symptom severity is frequently correlated with impairment, but not always. The lack of congruence between tic severity and impairment may be accounted for by the patient's ability to cope with severe symptoms and the availability of social support. When patients appear to be more impaired than his or her tic severity warrant, an extended evaluation focusing to identify co-occurring conditions or problems with social support may be necessary.

In addition to direct clinical observation, a number of structured and semi-structured instruments are available for the evaluation of tic symptom severity (Scahill et al. 2006). Assessment instruments, including the commonly used Yale Global Tic Severity Scale (Leckman et al. 1989), follow the clinical approach described above.

### Assessment of Co-occurring Conditions

Whereas tic severity and impairment are often correlated, many patients with mild tics are most impaired by the co-occurring conditions ADHD, OCD, and Learning Disorders (LD). An adequate assessment of these conditions is part of any comprehensive evaluation. The methods of assessment of these conditions are similar to those used in patients without TD. The exception is the assessment of tic-related obsessive-compulsive symptoms, for example, touching, tapping, rubbing, “evening up,” repeating actions, stereotypic self-mutilation, staring, echolalia, and palilalia. Although these symptoms are often omitted from the traditional psychiatric and neurological review of symptoms, tic-related obsessions and compulsions should always be part of the routine evaluation of patients with tics. Similarly, before the diagnosis of ADHD is made in a child with tics a review of the impact of tics, premonitory sensations, anxiety and obsessive-compulsive symptoms assures that impairment in attention and problems with motor restlessness are not secondary to other problems.

### Assessment of Other Psychiatric Disorders

It is standard for any psychiatric evaluation to rule out all other psychiatric disorders. In complex cases of TD, the multitude of behavioral and emotional symptoms can be formulated in a number of different ways. Behavioral and emotional problems can be seen as components of the TD diathesis, as a reaction to having a chronic disorder, or as part of an independent psychiatric disorder that is complicating the clinical picture. Clinical formulations that oversimplify and do not consider the presence of multiple independent disorders may lead to incorrectly attributing unrelated symptoms to TD and may result in diagnostic imprecision and treatment failures. It is important to identify all possible psychiatric disorders in patients with TD so that the hierarchy of disabling conditions can be identified and treatment initiated accordingly. For example, an older teenage boy with a long history of TD, ADHD, impulse
control and behavior problems, and a difficult relationship with his parents presents with increasing impulse control problems, intrusive sexual comments and behavior, insomnia, and substance abuse. Although it would be parsimonious to consider this clinical presentation an exacerbation of TD, it would be clinically prudent to rule out the presence of other treatable conditions, such as a substance use disorder, major depressive disorder, or bipolar disorder. A positive family history of one of these disorders would provide additional support for the diagnosis. Table 48–1 highlights some of the complex presentations often found in TD psychiatry and specialty clinics.

### Table 48–1 Complex Clinical Presentations in TD

| Tics + ADHD + OCD + LD + major depressive disorder |
| Tics + ADHD + OCD + LD + separation anxiety disorder |
| Tics + ADHD + OCD + LD + panic disorder |
| Tics + ADHD + OCD + LD + bipolar disorder |
| Tics + ADHD + OCD + LD + autism–pervasive developmental disorder |
| Tics + ADHD + OCD + LD + substance abuse |
| Tics + ADHD + OCD + LD + conduct disorder |
| Tics + ADHD + OCD + LD + personality disorders |

### Psychosocial Issues

Psychosocial issues can play a role in tic severity and in overall adaptation and impairment. Identification of a child’s strengths as well as areas of needed support provides the basis for a balanced understanding of the child. Assessment of family, peer, and school support along with assessment for the presence of opportunities to be intellectually, physically, and socially challenged is also important. The appropriate balance between support and challenge in children is critical for long-term development. An environment that is too protective limits opportunities for building skills. An environment that is too challenging can lead to frustration, anger, and maladaptive coping.

### Physical Examination

Tic assessment requires a careful evaluation of observable tic symptoms, however, the absence of tic symptoms during an evaluation is not uncommon and should not necessarily lead to clinical doubt. Tic expression is known to vary based on environmental factors and some patients are able to suppress symptoms for short periods of time (Piacentini et al. 2006). Beyond the observation of tic symptoms in the interview, there are no pathognomonic physical examination findings. Patients with TD have been noted to have nonfocal and nonspecific subtle neurological findings (“soft” signs). If tic suppression with antipsychotic agents is considered, a structured method for documenting complex movements at the pretreatment evaluation is useful in establishing a baseline. This approach aids in monitoring disease progression, treatment gains, or developing antipsychotic-induced movements.

### Laboratory Evaluation

No specific laboratory or imaging tests are helpful in making the diagnosis or assessing a patient with TD. Laboratory assessment maybe done as part of a routine health screen or in anticipation of medication interventions. Currently, laboratory testing for Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infection (PANDAS) and group A beta-hemolytic streptococcal (GABHS) infections include throat culture, if strep pharyngitis symptoms are present. Antistrept antibody titers and other screens for antineuronal antibodies are considered experimental at this time (Rizzo et al. 2006, Singer et al. 2005).

### Epidemiology

TD is recognized as a global phenomenon, suggesting that the prevalence, presentation, and course of TD are similar across countries, cultures, and ethnicities (Robertson 2003). However, great variability in assessment strategies, definition of impairment, treatment approaches, access to appropriate medical care, help seeking behavior and, importantly, acceptance of people with TD (i.e., stigmatization) likely exists and may explain differences in prevalence estimates in different countries, ethnic groups and over time.

The availability of more clearly defined diagnostic criteria and more rigorous epidemiological studies has improved prevalence estimates in recent years. Currently, tic disorders are considered relatively common with 4–18% of school-aged children affected (Robertson 2003). Tic disorders are more common in children than adults and people with mild symptoms are much more common than those with severe, complex symptoms. TD is currently considered to affect approximately 1% of school-aged children with males four times more commonly affected than females (Robertson 2003). The number of adults with severe tic disorders requiring tic suppression treatment is estimated to be approximately 0.1% (Scähill et al. 2001).

### Course of the Tic Disorders

Tic symptoms usually begin in childhood with an average age of diagnosis of 7 years. Even though current diagnostic criteria allow for an age of onset up to 18 years, it is unusual for symptom onset to occur during the teenage years and adulthood. Facial and ocular tics (i.e., blinking, squinting, eye darting, or eye rolling) typically appear first. In many patients, motor tics remain isolated to the face. Motor tics appearing in other anatomical regions often present sequentially from the head and face to the neck, shoulders, trunk, and extremities. Motor tics typically precede vocal tics. Initial tic symptoms (motor or vocal) are often simple in character, with complex symptoms developing later.

Longitudinal studies suggest that tic severity peaks during the latency age and early teen years. Most patients experience a subsequent decline in tic severity during the middle to late teenage years (Leckman 2003, Lin et al. 2007). Approximately, one-third of individuals with tic disorders will experience a complete remission of tics as they reach adulthood. Research has demonstrated that few patients experience a severe or deteriorating course (Leckman et al. 1998). Some research studies have indicated that marked or severe tics in childhood tend to persist into adulthood (Bloch et al. 2006), while others have found childhood tic severity to be a poor predictor of later severity (Leckman et al. 1998).
Co-occurring Symptoms or Disorders

Comorbidity

Tourette disorder can be complicated by a broad range of co-occurring emotional and behavioral problems (Gaze et al. 2006). Common co-occurring symptoms include attention and learning problems, obsessive-compulsive behaviors, difficulty with impulse control, depressed mood, anxiety, behavior problems, and substance use. In some patients, these problems reach diagnostic significance, but in others they are less severe. The most common co-occurring disorders are ADHD (50–60%) and obsessive-compulsive disorder (OCD; 30–70%). These co-occurring problems, when present, are typically more disabling than the tic disorder and are often the reason patients seek clinical services.

The exact relationship of these co-occurring conditions to TD is a matter of some controversy. Some conceptualize the TD phenotype narrowly (i.e., motor and vocal tics only), seeing co-occurring conditions as independent. Others subsume various co-occurring problems within a broad TD phenotype.

Careful attention to the TD phenotype is critical for scientific exploration of etiology and pathophysiology, but is also important for assessment and treatment. For patients whose symptoms meet TD diagnostic criteria, but who also have multiple co-occurring conditions (e.g., OCD, ADHD, and LD) a simple moniker—Tourette's disorder—can have great power for advocacy, but is an obvious oversimplification and can lead to poorly conceptualized treatment. Conceptualizing the same child as having TD plus OCD, ADHD, and LD may lack parsimony, but facilitates clear treatment hierarchies and hopefully more effective treatment strategies.

Despite the power that the TD diagnosis can have for advocacy, some caution is warranted. To illustrate, Billy, a bright and academically successful 11-year-old boy, had motor and vocal tics, but no co-occurring conditions. The diagnosis of TD was helpful at school with teachers becoming more understanding of his movements and sounds. However, as he approached middle school, he was not accepted into the gifted and talented program based only on the school's presumption that his TD might also relate to problems with attention and learning, anxiety and perhaps depression. In this example, the TD patient was inappropriately encumbered by the perception of an overly broad TD conceptualization. The opposite problem can also occur. Jesse was a 7-year-old boy who had moderately severe tics. The initial evaluation focused on tics and did not include a full assessment of common co-occurring problems. As such, moderate to severe OCD symptoms were overlooked. Jesse's clinician was comfortable with the diagnosis and treatment of TD and started him on an antipsychotic medication. Jessie experienced little to no reduction in tics, his OCD worsened, and he experienced increased impairment at home, school, and with his peers. Jesse was seen in consultation and his treatment was subsequently reoriented toward his OCD with symptom improvement following.

ADHD

Upward of 50% of clinically ascertained children and adolescents with TD may experience problems with attention, concentration, over-activity, or impulse control (Gaze et al. 2006). Relative to youth suffering from TD alone, those with TD + ADHD experience greater behavioral and social problems (Robertson 2006). The course of ADHD symptoms in persons with Tourette's syndrome (TS) is similar to that in children with ADHD only (Erenberg 2005). In both groups (i.e., TD + ADHD and ADHD only) symptoms of hyperactivity typically attenuate before puberty, whereas problems with attention and concentration may continue into adulthood. Additionally, ADHD symptoms usually precede the onset of tic symptoms in patients with TD + ADHD. The estimated frequency of ADHD in community samples is lower (8%) than in clinic populations (41%) (Apter et al. 1993, Caine et al. 1988, Erenberg 2005). The lowest prevalence estimate of ADHD in TD (8%), occurred in a sample of older teens assessed for current ADHD status, not lifetime diagnosis (Apter et al. 1993). Though the point prevalence of ADHD in this sample was more than twice than that in the general population, factors such as sample age and examination for current status probably led to an underestimate of lifetime ADHD in this population. The higher prevalence rates of ADHD in clinical compared to epidemiological samples raises the concern that clinical sample rates overestimate the true prevalence (Pauls et al. 1988).

With increasing awareness of the frequent co-occurrence of ADHD and TD more adults with these conditions are seeking treatment. Despite a growing literature on assessment methods and treatment of adults with ADHD, there is a lack of information on the prevalence, course, and impact of ADHD in adults with TD.

Obsessive–Compulsive Symptoms

Obsessions are stereotyped, persistent, and intrusive thoughts, impulses, or images that are experienced as unwanted and senseless by the affected individual. Obsessions commonly experienced by patients with OCD include fears of contamination, harm coming to oneself or others, losing control of one's impulses and being unable to remember important facts. Compulsions are repetitive behaviors or mental acts that an individual feels driven to perform in response to the obsession (American Psychiatric Association 2000). Compulsions commonly seen in OCD include repeated or stereotyped washing, grooming, checking (e.g., locks, switches, or doors), and other senseless rituals including counting, ordering, and hoarding. Because these thoughts and related behaviors are common in the general population, persons are considered “disordered” only when the obsessions or compulsions become time-consuming and impairing.

Differences in OCD symptoms in individuals with OCD alone and individuals with TD + OCD have been noted in several studies. Patients with TD + OCD tend to have greater concern with physical symmetry, ordering, exactness, and impulse control (Labad et al. 2007, Leckman et al. 1994). These concerns lead to what are termed tic-related compulsive behaviors and include “evening up” (e.g., ensuring that socks are pulled up evenly) and “just right” behaviors (i.e., arranging toys until it feels right) (Leckman et al. 1994, Leckman 2003). The absolute number of concerns appears to be greater in patients with TD + OCD compared to patients with OCD (George et al. 1993) (Table 48–2). Patients with TD + OCD typically report multiple concerns.
such as symmetry, violent or sexual images or urges, and worries about losing control. Patients with isolated OCD typically have a single concern, which their symptoms coalesce around (i.e., contamination, cleanliness, or hygiene). Some investigators have argued that the obsessions and compulsions in TD + OCD are more sensory–motor in character, whereas those in OCD are more cognitive and affective (Miguel et al. 2001, Miguel et al. 2000).

Recent factor analytic studies have identified common subtypes of OCD including: pure obsessions, contamination, symmetry/ordering, and hoarding groups (Baer 1994, Cullen et al. 2007, Hasler et al. 2007, Leckman et al. 2003). Subtype information serves to identify and define unique clinical presentations. For example, the contamination group is least comorbid with other psychiatric disorders and is more responsive to both behavioral and pharmacological treatments, whereas the hoarding group appears less responsive to treatment.

Although there are no longitudinal studies regarding the course of co-occurring obsessive–compulsive symptoms in persons with TD, the natural course of OCD symptoms includes worsening in adolescence and adulthood whereas TS symptoms tend to decrease as patients transition into adolescence and adulthood.

Relationship between TD and Commonly Co-occurring Symptoms
Research aimed at clarifying the relationship between TD and co-occurring conditions has yielded conflicting results. Some support a broad TD phenotype that includes numerous co-occurring conditions and symptoms (Comings 1995). Others support a circumscribed phenotype consistent with DSM-IV diagnostic criteria (Pauls et al. 1993). Despite the existence of divergent conceptualizations, there is general agreement that CTD (motor or vocal) is a milder form of TD and that some forms of OCD and ADHD are an alternative expression of the common genetic diathesis (LaBuda and Pauls 1993, Stewart et al. 2006). The relationship between TD and other psychiatric disorders (i.e., ODD, LD, MDD) is less clear. Some have argued that an ascertainment bias accounts for increased rates of other co-occurring conditions in TD (Pauls et al. 1993). Others argue that a common genetically based neurochemical abnormality underlies TD and various co-occurring conditions (Comings 2001).

### Differential Diagnosis

Tics disorders have many characteristics that differentiate them from other movement disorders (Jankovic 1992). Perhaps the most unique aspect of tics, in terms of differential diagnosis, is the presence of a childhood history of simple motor tics in the face. This presentation is not consistent with other movement disorders. Movement disorders such as chorea and dystonia are associated with continuous movements where as tics are intermittent. Other episodic, paroxysmal dyskinesias are more often characterized by choreiform and dystonic movements. Myoclonic movements and exaggerated startle responses are, like tics, brief and intermittent, but are usually large-muscle movements that occur in response to a patient-specific stimulus.

Complex tics can be more difficult to differentiate from other complex movements. In individuals with no clear-cut or simple motor tics, it may be difficult to differentiate complex motor tics or “camouflaged” tics (i.e., tics made to appear purposeful) from a mannerism, gesture, or stereotypy. Mannerisms or gestures typically lack the involuntary, repetitive, and stereotyped nature of tics. Stereotypies tend to occur more commonly (but not exclusively) in children and adults with developmental disabilities and mental retardation (Jankovic 1992). However, it is not uncommon in tertiary referral centers to treat developmentally disabled children and adults who present with both tics and stereotypies. It is also possible to have a tic disorder and another movement disorder. For example, tic movements can co-occur with dystonia. When tic symptoms have an atypical presentation, onset, course a consultation with a movement disorders expert is suggested.

### Etiology and Pathophysiology

#### Genetic Factors

A greater concordance rate for monozygotic than dizygotic twins in studies of TD provides powerful evidence for the genetic etiology of TD. Segregation analysis of family study data has been used to identify the exact pattern of genetic transmission and the range of phenotypic expression of TD. Early studies identified TD as an autosomal dominant condition, however, recent studies have identified a complex pattern of inheritance that includes multiple genes and environmental factors. Linkage studies of TD, based on the autosomal dominant assumption, have not been successful. Candidate gene studies based on neurotransmitter and cortico-striato-thalamo-cortical (CSTC) circuit hypotheses have also been unsuccessful in identifying the TD gene(s). Recently, results from a large study which used a complex, new computer program to combine multiple data sets and thereby assess linkage has resulted in promising results.

#### Twin Studies

Evidence from twin studies suggests an important role for both genetic and nongenetic factors in the development of TD. Two large twin studies (Price et al. 1985, Hyde et al. 1992) and a follow-up study (Walkup et al. 1987) showed high concordance rates in monozygotic twins for TD and for tic disorders. In both of the studies, the concordance rate for TD in monozygotic twins was more than 50%. When calculated for the presence of TD in one twin and any tic disorder in the other, concordance rates approached 100%.

concordance rate for monozygotic twins is also significantly higher than the concordance rate in dizygotic twins (Price et al. 1985), suggesting a powerful role for genetics in TD. However, twin studies have consistently identified significant differences in tic severity between twins in monzygotic pairs suggesting a role for nongenetic factors in the development of tic severity.

Segregation Analyses and Models of Inheritance

There have been a number of TD family studies which have been subjected to segregation analysis. (Comings and Comings 1987, Eappen et al. 1993, LaBuda and Pauls 1993, Pauls et al. 1991, Pauls and Leckman 1986). In contrast to early studies, which suggested TD was an autosomal dominant, single major gene condition, more recent studies suggest a more complex pattern of inheritance such as a mixed model (i.e., one major gene with contributions from minor genes and the environment) (Walkup et al. 1996) and an unrestricted, non-Mendelian model (Seuchter et al. 2000).

Linkage Studies

Despite a large number of linkage studies, no TD gene has been identified to date. A number of hypotheses have been offered to explain the inability of the linkage studies to reliably identify the TD gene(s) (Pauls 1992, Wilke et al. 1992). Linkage data analytic methods require definition of model parameters including mode of inheritance, gene frequency, penetrance, and rates of phenocopies all of which are either unknown or debated (Cerullo et al. 2007). As a result, linkage analyses which assume an autosomal dominant model of inheritance and low gene frequency may not be accurate if the pattern of inheritance is more complex or the gene is more common (Seuchter et al. 2000, Walkup et al. 1996). Other problems include errors in phenotypic identification of affected individuals leading to both false-positive and false-negative diagnoses. Diagnosing moderate to severe TD can be relatively straightforward, but milder cases, or cases in which there is no direct, observable evidence of tics during the interview are difficult to reliably evaluate.

Candidate Genes

Pursuing linkage at a specific site on the genome through the use of a candidate gene is another method for identifying the genetic locus of a given disorder. Choosing a candidate gene is often related to hypotheses regarding both the gene and the etiology of a given disorder. In TD, genes involved in the underlying neurobiology including CSTC circuit abnormalities, neurotransmitter systems (e.g., dopamine, serotonin, and the noradrenergic system) and synaptic proteins have been perceived as ideal candidate genes. Many candidate gene studies have utilized genes identified by the Human Genome Project. The vast majority of candidate gene studies have not found consistent associations (Cerullo et al. 2007, van de Wetering 1993). In the few positive studies, the candidate gene accounts for only a small portion of the risk (Grice et al. 1996) and none of these studies have been replicated.

Chromosomal Abnormalities

Nonfamilial cases of a disorder where there is also an identified chromosomal abnormality suggest a causative association regarding the development of a disorder. Pedigree data suggest that chromosomal abnormalities occur more frequently in family members of TD probands and may be a fruitful area of study. The SLTRK1 gene, a promising candidate gene, was found near an inversion at chromosome 13q (Abelson et al. 2005). The SLTRK1 has shown an overlapping expression pattern in brain regions previously implicated in TD and has been associated with abnormal dendritic growth in neuronal cells (Abelson et al. 2005, Grados and Walkup 2006, Züchner et al. 2006). Although the SLTRK1 finding is helpful in advancing our understanding of gene-based neural correlates of TD, it is not a major casual gene and its specificity to TD has recently been called into question (Wendland et al. 2006).

Tourette Syndrome Association International Genetics Consortium Sibpair Study

Sibpair studies offer a number of advantages over large family linkage studies or candidate gene studies. Sibpair studies do not require a specific hypothesis regarding mode of inheritance and gene frequency or a hypothesis regarding a specific genetic site’s involvement. The sibpairs method assumes that the genetic material shared by two or more affected siblings should include the genetic material associated with the development of the disorder. Collecting sibpair data allows researchers to identify the genomic sites of increased sharing among all the affected sibpairs and in turn leads to a decrease in the number of sites likely to be associated with the condition under study. The sibpair method is less sensitive to misdiagnoses and modeling assumptions and has been successfully used to identify the multiple genes involved in juvenile-onset diabetes (Davies et al. 1994).

The first sibpairs study of TD identified two sites with maximum likelihood scores (MLS) of >2 (>99/100 chance of being true). The identified sites were on chromosome 4q and 8p (The Tourette Syndrome Association International Consortium for Genetics 1999). Although these results suggest that TD genetic material may be in these regions, MLS of >3 (>99/1000 chance of being true) are typically the threshold for meaningful significance in genetic studies due to the considerable potential for chance findings.

Subsequent to these findings, the Consortium conducted the largest genetic linkage study yet undertaken. In this study, independent sibpairs and separate multigenerational families were collectively examined (N total = 2,040). Results demonstrated strong linkage to a region on chromosome 2p23.2 (− log p = 4.42, p = 3.8 × 10−3) at marker D2S144 for both sibpairs and multigenerational relatives with Tourette’s or chronic tic disorders (The Tourette Syndrome Association International Consortium for Genetics 2007). Further exploration of this genetic region is currently underway.

Neurobiology of TD

Most speculation regarding sites of neurological dysfunction in tic disorders have focused on the basal ganglia (BG) and bidirectional connections between the frontal cortex and limbic system. Abnormalities in these structures, interconnections, or neurotransmitter substrates could readily cause the wide variety of motor, sensory–motor, cognitive, and affective symptoms seen in patients with TD (Cerullo et al. 2007, Singer and Walkup 1991). Elucidating the nature and location of neuroanatomical dysfunction in TD
is facilitated by sophisticated imaging methods, including functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and single photon emission tomography (SPECT) as well as increasing access to high-quality postmortem brains. These techniques have revealed subtle abnormalities in the BG, cortical, and limbic regions of the brain in subjects with TD relative to controls. Despite the excitement of these initial findings, there is, to date, no characteristic anatomical abnormality that can be used for diagnosis.

**Neuroanatomical Abnormalities**

Existing functional neuroimaging studies suggest that TD is broadly characterized by dorsal premotor and motor area cortical hyperactivity, BG hypometabolism and hypoperfusion, and paralimbic abnormalities (Butler et al. 2006). More specifically, TD is associated with decreased caudate and thalamic activity, coupled with increased activity in the lateral and medial premotor cortex, supplementary motor areas, anterior cingulate gyrus, dorsolateral-rostral prefrontal cortex, inferior parietal cortex, putamen, caudate, primary motor cortex, Broca’s area, superior temporal gyrus, insula, and claustrum (Shavitt et al. 2006). Motor tics have been linked to excess thalamic excitation and/or impaired sensorimotor cortical inhibition (Cerullo et al. 2007, Stern et al. 2000). Vocal tics appear to be associated with activity in the post-rolandic language regions, insula, caudate, thalamus, and cerebellum (Stern et al. 2000).

Imaging studies have identified left–right asymmetry in the BG (i.e., larger left-sided BG structures) (Singer et al. 1993, Peterson et al. 1993, Peterson et al. 2003). Although MRI studies have demonstrated larger dorsolateral prefrontal regions in children with TD, these regions were smaller for adults with Tourette’s. Interestingly, Bloch (2005) in a retrospective longitudinal magnetic resonance imaging (MRI) study (average follow-up interval = 7.5 years) demonstrated that caudate nucleus volumes were significantly and inversely correlated with the persistence of tic (and OCD) symptom severity in early adulthood, but not with severity at the time of initial evaluation. This finding may link tic and OCD symptom persistence in adulthood with morphological disturbances within the BG, but may also represent an adaptive rather than pathogenic process (Gerard and Peterson 2003).

Brain scans during voluntary tic suppression and the natural state may be another approach to identify regions of interest. Brain regions with large changes in signal intensity included the BG, thalamus, and cortical regions associated with attention-demanding tasks (Peterson et al. 1998). Functional neuroimaging studies have demonstrated that the deactivation of the areas in the ventral BG (i.e., putamen and globus pallidus) in addition to partial activation of the prefrontal cortex and dorsal BG (i.e., caudate nucleus) are involved in voluntary tic suppression (Shavit et al. 2006).

Imaging studies focused on identifying differences between males and females with TD document a lack of normal asymmetry in the globus pallidus in males, but not in females (Singer et al. 1998). Differences between males and females in corpus callosum morphology were not replicated in a comparison of subjects with TD only, TD + ADHD and matched controls (Zimmerman et al. 2000).

Anatomical studies of postmortem brain specimens have been limited by the few brains available. In a study of a single brain specimen, a pattern of immature cell development was noted in portions of the BG (Haber et al. 1986).

**Neural Circuitry Abnormalities**

There is a growing body of evidence that supports the hypothesis that TD is caused by dysregulation of CSTC circuits. Impaired cortical inhibition of motor movements could be caused by decreased cortical activity resulting from brainstem input (Cerullo et al. 2007). Excess thalamic activity has also received considerable attention in the literature. Either hyperactivity of the direct pathway (i.e., striatum to globus pallidus interni (GPi)/substantia nigra pars reticula (SNpr) to the thalamus and cortex) or hypopactivity of the indirect pathway (i.e., striatum to globus pallidus externa (GPe) to subthalamic nucleus to GPi/SNpr), could result in excess movement via disinhibition of thalamo-cortical motor pathways (Butler et al. 2006) (see Table 48–3 and Figure 48–1).

Several studies have demonstrated BG hypometabolism and hypoperfusion, which suggests indirect pathway dysfunction in TD. Despite this intriguing possibility, it has been argued that such a model cannot adequately account for the waxing and waning course of TD.

It has been proposed that by examining matrisomes (i.e., specific areas of functional homogeneity) researchers

may be able to further refine the CSTC model to account for the repetitious and stereotyped nature of tics as well as the waxing and waning course. One proposed hypothesis is that matrisomes become abnormally active resulting in the inhibition of the normal suppression of unwanted movement by the ventral BG. Stated differently the ventral BG inhibition results in disinhibition of the thalamo-cortical circuits leading to the production of tics (Mink 2006).

Electroencephalogram (EEG) studies are useful to understand the timing and sequence of cortical events. It is also is helpful in understanding the relationship of cortical and subcortical structures (i.e., cortical coherence). It has been shown that there is increased cortical coherence between sensorimotor areas and the prefrontal and mesial frontal cortex during voluntary tic suppression (Serrien et al. 2005). Enhanced frontomesial networks in TD may reflect a change in brain function associated with tic suppression.

### Neurochemical Abnormalities

A number of neurochemical abnormalities underlying TD have been proposed based on observations that some pharmacological agents reduce tics. Tic suppression with dopamine blockers such as haloperidol and alpha-adrenergic agonists such as clonidine have implicated the dopamine–acyethylcholine and adrenergic systems, respectively. Similarly, the serotonin system has been implicated due to the positive therapeutic effect of selective serotonin reuptake inhibitors (SSRIs) in patients with OCD. The specific role of various neurotransmitters and related receptors in TD remains unclear. It is possible that they have a primary role or are secondary to abnormalities in circuitry or specific brain regions. In addition, a better understanding of the neurotransmitters involved in BG interconnection are leading to some improvement in conceptualizing how medication might impact brain functioning.

### Dopamine

Much of the support for the role of dopaminergic overactivity in TD stems from observations that pharmacological agents that diminish dopaminergic activity also decrease tic severity in patients with TD. The majority of speculation regarding the mechanism of dopaminergic overactivity in TD has focused on either dopamine excess or dopamine receptor hypersensitivity.

In the first proposed mechanism, excess dopamine activity (DA) causes hyperexcitation of thalamic neurons and hyperstimulation of the cortex. In contrast, the second proposed mechanism suggests that excess DA activity in the ventral tegmental area (VTA) causes increased activation in the frontal cortex via mesocortical pathways leading to diminished inhibition (Cerullo et al. 2007). However, enhanced DA activity could also result from striatal supersensitive postsynaptic receptors, dopamine hyperinervation, increased presynaptic DA production and release, elevated release without increased presynaptic production, or cortical DA abnormalities (Cerullo et al. 2007). PET and single-photon emission computed tomography (SPECT) studies of TD patients have found an increase in presynaptic dopamine, DA transporters, postsynaptic DA D2 receptors, and greater DA release in the BG relative to health controls (Singer et al. 2005).

A study by Minzer et al. (2004), identified increase densities of D2 and dopamine transporter (DAT) in the prefrontal cortex of patients with TD. Increased DA stimulation in the striatum and subsequently the thalamus and cortex may lead to tic symptoms. Additionally, D2 receptor activation on inhibitory neurons would in turn disinhibit pyramidal cells leading to striatal overstimulation and tic formation (Minzer et al. 2004).

### Serotonin

There are few definitive studies on the role of other neurochemical systems in TD. However, because pharmacological agents that impact serotonin activity are associated with benefits in OCD symptom severity the serotoninergic system has been implicated in TD. Further evidence comes from postmortem brain studies demonstrating trends toward decreases in levels of serotonin, its precursor tryptophan, and its primary metabolite 5-hydroxyindoleacetic acid, in subcortical regions (Anderson et al. 1992) in spite of normal levels in the cerebral cortex (Singer et al. 1990). These findings, in conjunction with presumably normal and significant serotoninergic innervation of the striatum, suggest possible abnormalities of the metabolism of serotonin and its precursor tryptophan (Albin 2006, Anderson et al. 1992).

### Norepinephrine

Following the success of alpha-2 agonists (i.e., clonidine) in reducing tic severity, there has been a surge in interest regarding norepinephrine in tic generation. To date, little is known about the precise role of norepinephrine in TD; however, noradrenergic fibers project widely to the prefrontal cortex from the locus ceruleus (Singer and Minzer 2003).

### Glutamate

It has been suggested that a primary role of dopamine in the striatum is to modulate glutamatergic corticostriatal neurotransmission. Moreover, it has been postulated that the close proximity of dopaminergic and glutamatergic terminals may create cross modulation of neurotransmission both pre and postsynaptically (Albin 2006). Additionally, animal studies have lead to hypotheses regarding the role of

![Figure 48–1 Neurotransmitters of the Direct and Indirect Pathways. Glutaminergic pathways are in black, dopaminergic pathways are in light red, and GABA pathways are in dark red.](image-url)
excessive forebrain glutamate production and TD (McGrath et al. 2000).

Opiates
The opioid system has a role in movement control and is localized within the BG. A preliminary postmortem brain study identified a decrease in levels of the opioid dynorphin A in striatal fibers projecting to the globus pallidus (Haber et al. 1986). The finding of decreased dynorphin in brain tissue has not been replicated and is difficult to accept in light of a report of elevated cerebrospinal fluid dynorphin A concentrations in patients with TD compared with control subjects (Leckman et al. 1988). The effectiveness of opiate antagonists in the treatment of patients with TD is mixed; some investigators report improvement (Sandyk 1985), and others report few responders (Erenberg and Lederman 1989).

Social/Environmental Factors in the Etiology of TD
Evidence supporting a genetic etiology for TD is compelling; however, there is also evidence that environmental factors may interact with genes in tic symptom development, expression, and severity. Environmental factors associated with increases in symptom severity can occur throughout development and include prenatal development. Studies of Tourette's subjects show protracted vomiting by a subject's mother during pregnancy (Leckman et al. 1990) or prenatal exposure to androgenic hormones may be a factor in the development of a new tic symptom (e.g., post-nasal drip). It is not uncommon for persons with TD to identify specific environmental stimuli which elicit particular tic symptoms (e.g., a particular class in school), precede a bout of symptoms (e.g., increases in room temperature) or precede the development of a new tic symptom (e.g., post-nasal drip). Clinical wisdom also suggests that stressful or exciting life experiences may increase tic symptoms whereas soothing activities requiring or those requiring sustained attention tend to decrease tic symptoms. In addition there is emerging behavioral theory which suggests that environmental factors can shape tic symptoms severity and complexity over time. This theoretical approach to tic symptom severity has been stimulated both by the apparent efficacy of behavioral treatment for tic severity and emerging findings in neuroscience suggesting that the neurocircuity involved in TD has the capacity for adaptation/learning (Graybiel 2005).

Autoimmunity and TD
In several reports (Kiessling et al. 1993, Swedo et al. 1994), the development of tics as well as obsessive–compulsive symptoms in children and adolescents have been associated with group A GABHS infection. The underlying mechanism is proposed to be similar to that involved in the development of Sydenham's chorea, in which antibodies developed in the course of infection cross-react with BG tissue, resulting in the characteristic choreiform movement disorder of Sydenham's. In Sydenham's chorea there was often a time lag of 1–9 months between acute infection and the development of the characteristic movement disorder. Patients with TD and OCD were described as having increases in tics and obsessive–compulsive symptoms in association with a recent history of a streptococcal infection or elevated antistrep antibodies. Case reports have also described subjects with the abrupt onset or exacerbation in symptoms occurring in parallel with antibody increases and with MRI changes in caudate size (Giedd et al. 1996). These cases have been given the acronym PANDAS (Swedo et al. 1998). However, two recent prospective longitudinal studies did not demonstrate a clear linkage between GABHS infection and the development of tic symptoms (Luo et al. 2004, Perrin et al. 2004). Moreover, a pilot study regarding the use of prophylactic penicillin to prevent neuropsychiatric exacerbations in children who had PANDAS was unsuccessful (Garvey et al. 1999). Finally, while penicillin and azithromycin prophylaxis was found to be effective in decreasing streptococcal infections and subsequent neuropsychiatric symptom exacerbations in children in a PANDAS subgroup (Snider et al. 2005), others have raised methodological concerns regarding relatively small sample size and the lack of a pill placebo control (Budman 2005).

As a result of recent findings, the PANDAS–TD link remains controversial. Skeptics suggest that the possibility of chance association is high given that tics, obsessive–compulsive symptoms, and streptococcal infections are common events in childhood. Despite some negative findings, more research is necessary to further explore the relationship between PANDAS and TD.

Treatment

Standard Approaches to Treatment

Educate the Patient and Family about Tic Disorders
Given the difficulties patients and their families often experience before finding appropriate care, the initiation of treatment can be a delicate process. Many families are frightened by the implications of childhood “neuropsychiatric” disorders and often envision a grim prognosis. After the initial evaluation is complete it is essential to provide general education regarding the course, treatment, and prognosis for tic disorders to allay fears (Table 48–4). Most patients and families find comfort in knowing that the majority of persons with tics have consistent improvement in tic severity as they progress through adolescence and into adulthood. They are also pleased to hear that tic symptoms are often not physically or psychologically impairing and that only a small portion of patients are significantly disabled directly as a result of tic symptoms. In this regard, it is often helpful to
cite examples of sports personalities or other public figures that have identified themselves as having TD and are doing well both personally and professionally.

**Educate the Family about Co-occurring Disorders**

Once issues and concerns regarding the tics are discussed and clarified, the focus shifts to the to co-occurring conditions. Treating co-occurring ADHD, LD, and OCD is especially important because they are often the most impairing conditions. The transition from discussing tic suppression to treating co-occurring problems is often complicated. Patients, families, and psychiatrists understandably are focused on tic symptoms. Tics are easily observable and a clear target for medication management. Co-occurring conditions, especially internalizing disorders, have less obvious symptoms and are more challenging to treat when identified. However, failure to correctly identify co-occurring conditions is perhaps the most common pitfall in TD treatment. Pursuing tic suppression without treating co-occurring conditions may not lead to optimum outcome.

**Create a Hierarchy of the Clinically Impairing Conditions**

Creating the hierarchy of the most impairing conditions is the next major step in treatment. Psychiatrists typically create some clinical hierarchy for treatment as part of their initial formulation. In TD, it is essential that a conscious effort be made to formulate, organize, and create treatment hierarchies which appreciate the potential multiplicity of complex clinical presentations. For example, children with moderate tics, separation anxiety with associated school refusal should initially be considered for a SSRI for separation anxiety and behavioral treatment for school refusal rather than antipsychotics for tic suppression (The Research Units on Pediatric Psychopharmacology Anxiety Study Group 2001). This example is prioritized in this way because it is possible that successful treatment of anxiety may reduce substantial impairment and may have secondary effects on tic symptom severity.

**Treat the Impairing Conditions**

This section focuses on the basic strategies for tic suppression followed by treatment of common co-occurring disorders. As most psychiatrists are familiar with the treatment for specific disorders particular emphasis is placed on the complexities of clinical management in this section.

**Tic Suppression: Pharmacological**

Reduction in tic symptom severity rather than the elimination of tics is the goal of pharmacological intervention (see review: Scahill et al. 2006). Haloperidol, a typical antipsychotic has been used for more than 30 years to effectively suppress motor and phonic tics. Since haloperidol, several additional first and second generation antipsychotics have been shown to be effective in the treatment of tic symptoms including fluphenazine, pimozide and risperidone. In Europe, the substituted benzamides, sulpiride and tiapride, have also been shown to be useful.

As new antipsychotic medications become available, clinical trials for tic suppression invariably occur. Of the second generation antipsychotics, risperidone appears to be most effective. Evidence for the efficacy of olanzapine and quetiapine has been mixed. Open trials and case series with clozapine are few, but uniformly negative. Antipsychotics with unique mechanisms of action such as aripiprazole and tetrabenazine may also be effective for tic suppression. The major drawback of antipsychotic medications is the frequent and significant side effects. Given the limitations of antipsychotic medications, efforts to identify other tic-suppressing agents are ongoing. Other medications that demonstrate efficacy are described below.

**Haloperidol.** Haloperidol is a high-potency antipsychotic that preferentially blocks dopamine D2 receptors. Historically, haloperidol has been considered the treatment of choice for tic suppression. It is effective in a clear majority of patients, but relatively few patients appear to tolerate the side effects to obtain tic-suppressing benefits. Doses of haloperidol in the range of 1–4 mg/day are usually adequate for tic suppression. Starting dosages are low (0.25–0.5 mg/day), with small increases in dose (0.25–0.5 mg/day) every 5–7 days until tic symptoms are manageable. Haloperidol is usually given at bedtime, but with low doses, some patients may require twice-a-day dosing for optimal tic control.

Side effects include those commonly seen with antipsychotics, such as sedation, extrapyramidal symptoms including acute dystonic reactions and akathisia, weight gain, cognitive dulling, and anticholinergic side effects. There have also been reports of subtle, difficult to recognize, side effects with antipsychotics including clinical depression, separation anxiety, panic attacks, and school avoidance (Bruun 1988). Dose reduction is the most prudent response to side effects, although the addition of anticholinergic medications for the extrapyramidal symptoms can be useful.

Dose reduction in individuals who have been administered antipsychotics long-term may be complicated by withdrawal dyskinesias and significant tic worsening or rebound. Withdrawal dyskinesias are choreothetoid movements of the orofacial region, trunk, and extremities that appear after antipsychotic discontinuation or dosage reduction and tend to resolve in 1–3 months. Tic worsening beyond pre-treatment baseline level (i.e., rebound) can last up to 1–3 months after discontinuation or dose reduction. Withdrawal symptoms can be mitigated by slow downward adjustment of antipsychotic medications. Tardive dyskinesia, which is similar in character to withdrawal dyskinesia, is most often develops during the course of treatment or is “unmasked” with dosage reductions. Due to relatively low dosages, rarely have cases of tardive dyskinesia been reported in patients with TD.

**Fluphenazine.** Fluphenazine has D2 and D1 receptor-blocking properties that may make it a more ideal
compound for tic suppression. In clinical trials fluphenazine has demonstrated similar efficacy for tic suppression, but milder side effects compared to other antipsychotics including haloperidol (Borison et al. 1982), even with long term treatment (Silay et al. 2004). Fluphenazine is slightly less potent than haloperidol so starting doses are somewhat higher (0.5–1 mg/day), as are the range of treatment doses (1.5–10 mg/day).

**Pimozide.** Pimozide is a potent and specific blocker of dopamine D2 receptors. Its side effect profile is generally similar to that of the other antipsychotics, although it appears to have fewer sedative and extrapyramidal side effects than haloperidol. In contrast to other haloperidol or fluphenazine, pimozide has calcium channel blocking properties that can affect cardiac conduction times. The co-administration of other medications that affect cardiac conduction, such as the tricyclic antidepressants (TCAs), is generally contraindicated. Baseline and follow-up electrocardiograms are important for adequate management of patients. Beginning treatment with a dose of 0.5–1 mg/day is prudent, although with pimozide’s long half-life, every-other-day dosing can be used to decrease the effective daily dose. Increases of up to 1 mg/day can occur every 5–7 days until symptoms are controlled. Most patients experience clinical benefit with few side effects with doses of 2–6 mg/day. Higher doses can be associated with more side effects. Studies comparing pimozide and haloperidol in patients with TD document benefit for both but no clear superiority of one over the other (Sallee et al. 1997, Shapiro et al. 1989). Pimozide at 1–4 mg/day was also useful in decreasing tics and improving some aspects of cognition that are commonly impaired in ADHD (Sallee and Rock 1994). The potential to have impact on both TD and ADHD symptoms with a single drug is an advantage that pimozide may have over other antipsychotics.

**Sulpiride and Tiapride.** Both of these agents are substituted benzamides available only in Europe. Like pimozide, they are unique in their combination of relatively specific dopamine D2 receptor-blocking activity and the potential for reduced risk of extrapyramidal symptoms and tardive dyskinesia. Typical starting dosages of tiapride are 50–100 mg/day with typical daily dosages ranging 150–500 mg/day. Sulpiride is typically started at 100–200 mg/day with daily dosages ranging 200–1000 mg/day. While both agents have demonstrated efficacy in tic suppression (Eggers et al. 1988, Robertson et al. 1990), it is unlikely that these agents will become available in the US.

The second-generation antipsychotics appear to have replaced the first-generation antipsychotics as the mainstay of treatment for the psychotic disorders. Given the potentially lower risk for tardive dyskinesia, atypical antipsychotics have also been assessed for tic suppression in patients with TD. Recent concerns about weight gain and metabolic side effects have dampened the enthusiasm for these agents. To date there are only small controlled or open trials to guide the clinician in the use of these agents.

**Risperidone.** Risperidone has been effective in reducing tic symptom severity in two controlled trials (Dion et al. 2002, Scahill et al. 2003) and may have the added benefit of augmenting SSRIs in treating tic-related OCD (McDougle et al. 2000). Dose adjustment of risperidone is similar to other antipsychotics – start with low dose risperidone at 0.25–0.5 mg/day with upward adjustments every 5–7 days to 1–4 mg/day in single or divided doses until adequate tic suppression is achieved.

**Ziprasidone.** The side effects, especially weight gain, have dampened the enthusiasm for the second generation antipsychotics risperidone, olanzapine, and quetiapine. In a small double-blind placebo controlled pilot-study (N = 8) with children and adolescents, ziprasidone was found to be effective in reducing tic symptoms with dosages ranging 5–40 mg/day (Sallee et al. 2000). The mean daily dose at the end of treatment was 28 ± 10 mg/day. There were few side effects including a low incidence of weight gain, however, some subjects experienced somnolence and akathisia at higher dosages (i.e., 40 mg/day), which were resolved by lowering the dosage. Concern regarding the impact of ziprasidone on cardiac conduction times especially QTc was not supported in this trial (Sallee et al. 2000).

**Olanzapine.** Olanzapine in low doses does not appear to have the same tic-suppressing power as the first generation antipsychotics which may be related to olanzapine’s relatively weak dopamine D2 blocking activity. An open-label study suggests that olanzapine can effectively control tic symptoms at final average dosages of 10.9 mg/day (Budman et al. 2001). Starting olanzapine dosages are typically 2.5–5.0 mg/day, with eventual daily dose ranging 2.5–12.5 mg/day.

**Quetiapine and Aripiprazole.** To date, only open case series of quetiapine and aripiprazole are available. When used, typical starting dosages for quetiapine are 25–50 mg/day, with typical daily dosages ranging 75–150 mg/day. As dosing strategies have changed since quetiapine was launched, higher doses may be more effective but have not been studied. As for aripiprazole, starting dosages have ranged from are 2.5–5.0 mg/day, with typical daily dosages ranging 10–20 mg/day.

**Clonidine and Guanfacine.** There is a long history of the use of the α2-adrenergic agonist clonidine for suppression of tics and ADHD symptoms. Whereas controlled trials have shown that some patients benefit with symptom reduction, the overall effect of clonidine for tic suppression and ADHD is more modest than that achieved with the “gold standards” (haloperidol and the stimulants, respectively) for these conditions (Goetz 1993). Given clonidine’s mild side effect profile, it is often the first drug used for tic suppression, especially in those children with TD and ADHD.

Treatment is initiated at 0.025–0.05 mg/day and increased in increments of 0.025–0.05 mg/day every 3–5 days or as side effects (sedation) allow (Scahill et al. 2006). Usual effective treatment doses are in the range of 0.1–0.3 mg/day and are given in divided doses (4–6 hours apart). Higher doses are associated with side effects, primarily sedation, and are not necessarily more effective. The onset of action is slower for tic suppression (3–6 weeks) than for ADHD symptoms. Side effects, in addition to sedation, include irritability, headaches, decreased salivation, and hypotension and dizziness at higher doses. Interestingly, owing to clonidine’s short half-life, some patients experience mild
withdrawal symptoms between doses. More severe rebound in autonomic activity and tics can occur if the medication is discontinued abruptly (Leckman et al. 1986). Some patients find that clonidine and guanfacine in the transdermal patch form provides a more stable clinical effect and avoids multiple doses each day. Children are usually stabilized on oral doses before they are switched to the patch. A rash at the site of the patch is a common complication of treatment.

Guanfacine is an alpha-2-adrenergic agonist that potentially offers greater benefit than clonidine for tic suppression because of differences in site of action, side effects, and duration of action. On the basis of animal models, it is hypothesized that guanfacine is likely to have a greater impact on attention without the significant sedation associated with the nonselective alpha-2-adrenergic agonist clonidine (Arnsten et al. 1988). Guanfacine’s long half-life offers the advantage of twice-a-day dosing, which is more convenient than the multiple dosing required with clonidine (Scahill et al. 2001). Starting doses are 0.5 mg/day with increases of 0.5 mg every 5–7 days up to 3–4 mg/day.

Benzodiazepines. Benzodiazepines can be useful in decreasing co-occurring anxiety in patients with TD and as an adjunct to SSRIs for OCD in TD. In addition, clonazepam appears also to be somewhat useful in tic reduction for Tourette’s and ADHD patients. In a small study examining the benefit of clonazepam as an adjunct to clonidine, dosages of 0.5–4 mg/day (in 2–3 divided doses) was associated with additional tic reduction in children and adolescents without deleterious effects on ADHD symptoms (Steingard et al. 1994). Because sedation is a significant side effect at these dosages, an extended titration phase of 3 to 6 months may be necessary. Similarly, a slow taper is required to avoid withdrawal symptoms (Goetz 1992). As clonazepam has a long half-life, once a day dosing is possible chronically.

Pergolide. Agonist activity on presynaptic dopamine receptors results in decreased dopamine release and may result in decreased tic severity in people with TD. A variety of dopamine agonists have been used in single case studies with mixed results. Pergolide, a mixed dopamine agonist used for treating Parkinson’s disease and restless leg syndrome has recently been removed from the market due to concerns regarding the development of cardiac fibrosis. Small clinical trials demonstrated modest efficacy of pergolide for tic suppression (Gilbert et al. 2000, Gilbert et al. 2003).

Other Somatic Treatments. Case reports of successful electroconvulsive therapy (ECT) treatment in patients with TD have described significant co-occurring conditions including OCD and psychotic symptoms (Karadenizli et al. 2005, Trivedi et al. 2003) and exacerbations of TD concurrent with the onset of severe depression in adulthood (Rapport et al. 1998). The effective use of ECT for appropriate indications (i.e., psychosis and severe depression) in people with TD should not be surprising and suggests ECT may be used successfully when TD is complicated by co-occurring conditions that are potentially responsive to ECT.

Repetitive transcranial magnetic stimulation (rTMS) has been used experimentally in OCD, depression and TD. Case reports in TD document that rTMS appears to be a safe procedure, but of variable efficacy (Chae et al. 2004, Orth et al. 2005, Mantovani et al. 2006). Trials that described minimal benefit used a short course (i.e., 1–2 treatments/2400 pulses) of 1HZ stimulation in the motor and premotor areas and led investigators to conclude that while rTMS may be a promising treatment, different approaches may be required to be effective (Orth et al. 2005). In a departure from previous trials, Mantovani et al. (2006) demonstrated good benefit using a longer course of treatment (i.e., 10 days/12,000 pulses) of 1HZ stimulation at a different site—the supplemental motor area.

Infection and Autoimmune-Based Treatments. Several treatment studies have been undertaken based on the hypothesis that some forms of TD or OCD may be an autoimmune reaction to Group A β-hemolytic streptococcal infection. Based on the beneficial effects of penicillin prophylaxis in preventing recurrences of rheumatic fever, a similar strategy was employed in a crossover design in subjects meeting criteria for PANDAS (Garvey et al. 1999). Garvey et al. (1999) found no differences in neuropsychiatric symptom improvement between the penicillin and placebo groups. However, these findings should be viewed with caution as there were several methodological flaws in this study including inadequate baseline assessment, incomplete prophylaxis in the PCN arm and carry over effects due to the crossover design. In regard to the later, penicillin given during the first “active” phase may have provided continued protection against streptococcal-triggered exacerbations in the second “placebo” phase. A second study of antibiotic prophylaxis used a longer but retrospective baseline and a parallel group design of two active agents but did not include a placebo arm so no conclusion about the antibiotic prophylaxis can be drawn from this study (Snider et al. 2005).

After small open trials with immunomodulatory treatments such as plasma exchange or intravenous immunoglobulin (IVIG), a larger trial comparing these methods to sham IVIG was undertaken (Perlmuter et al. 1999). At 1 month, the IVIG and plasma exchange groups demonstrated improvements in obsessive-compulsive symptoms. The plasma exchange group also demonstrated reductions in tic symptoms at one month. At one-year follow-up, symptoms remained improved from baseline on all measures for both the IVIG and plasma exchange groups, with the most meaningfully significant improvements in obsessive-compulsive and tic symptoms. Although this study is encouraging, there are a number of methodological problems that caution against the use of these treatments in clinical practice (Singer 1999). The most significant being a broken blind in the IVIG and placebo groups due to obvious active treatment side effects including nausea, vomiting, and headaches.

**Tic Suppression: Nonpharmacological**

**Habit Reversal Training (HRT).** Although pharmacological interventions remain the first-line treatment for tic disorders, evidence suggests that HRT is effective for tic suppression (Himle et al. 2006). Behavioral interventions for tics combine anecdotal reports from adults with TD regarding the use of particular strategies to decrease tic severity and principles of learning theory. One of the great benefits of behavioral treatment is their compatibility with medication and other psychosocial treatments such as exposure and
response prevention for OCD. Behavioral treatments for tic management can be used as a first-line treatment, an alternative to medication or as an adjunct to medication in those who have had a partial response or cannot tolerate higher or more effective doses of tic suppressing medication.

From the perspective of HRT, tics can be triggered, exacerbated and potentially maintained by environmental stimuli such as specific settings, interpersonal interactions, emotions, cognitions, and other internal experiences, consistent with the stimulus-response pattern of classical conditioning. Furthermore, as tics are known to momentarily relieve the discomfort associated with premonitory sensation, the tic behavior can thus be shaped and elaborated via negative reinforcement.

HRT was initially described by Azrin and Nunn in 1973. The two principle components of HRT are awareness training and competing response training. Awareness training involves learning to become aware of and eventually monitor premonitory urges (e.g., building tension, tickle, itch, etc.) and subsequent tic behavior (e.g., head shaking). Competing response training involves learning to perform an alternative behavior utilizing the same muscle groups used to carry out the tic. An appropriate competing response is one that is socially acceptable, relatively inconspicuous, does not cause pain, and can be held for at least a minute or until the urge dissipates. The purpose of HRT is to disrupt reinforcement cycles by performing an alternative and less conspicuous behavior (i.e., competing response) when facing triggering stimuli. Once the reinforcement cycles are interrupted and tics decrease in frequency and severity, the voluntary competing response can be stopped. To illustrate, a patient with a premonitory sensation in the shoulder would voluntarily tense the opposing shoulder muscle (competing response) for a minute or until the urge dissipates. The purpose of HRT is to disrupt reinforcement cycles by performing an alternative and less conspicuous behavior (i.e., competing response) when facing triggering stimuli. Once the reinforcement cycles are interrupted and tics decrease in frequency and severity, the voluntary competing response can be stopped.

Published clinical trials of HRT (approximately 200 patients in total) evidence marked reductions in tic frequency with treatment gains maintained at follow-up. Interestingly, patients also report decreases in premonitory urges with successful treatment. As a result of these studies HRT has been classified as “probably efficacious” according to the American Psychological Association’s 1995 Task Force on Promotion and Dissemination of Psychological Procedures (see Carr and Chong 2005). Although evidence is accumulating to support the efficacy of HRT, the variability in subject recruitment, interventions and assessment of outcome suggest larger and more definitive studies are needed.

There are no published, systematic studies of other psychosocial interventions for tic reduction in patients with TD. Case reports of massed practice—repeating the tic voluntarily over and over until severity decreases—have not demonstrated efficacy. Most current treatment efforts are based on a combination of traditional psychosocial interventions, clinical judgment, and psychoeducation. Behavioral training in the form of neurofeedback is an emerging treatment that has yet to establish clinical utility.

Individual and Family Psychotherapy. Individual psychotherapy can be useful for support, development of awareness, or addressing personal and interpersonal problems more effectively. Appropriate areas for psychosocial intervention are best identified by a functional assessment and targeting domains of impairment.

Family therapy can be useful when families have problems adapting, interacting and communicating. Although psychoeducation is beneficial for most families, some have problems fully appreciating the involuntary nature of tics and may inadvertently create a harsh or critical environment. Parents may also inadvertently lower general expectations due to confusion regarding what constitutes tic symptoms. Variability among professionals regarding what constitutes tic related behaviors leads some parents to conceptualize all maladaptive behaviors as involuntary and therefore fail to hold their children responsible for non-tic behaviors. Parents also decrease expectations in an effort to minimize stress on their child with tic disorders. For children with TD to do well, they need support from their family to develop effective self-control in areas not affected by TD so that optimal adaptation can occur.

In newly diagnosed adults, psychotherapy oriented toward adequate adjustment to the diagnosis is important but not always easy. Adult patients frequently experience a mixture of relief and anger or resentment related to their past experiences with inadequate assessment, incorrect diagnosis and discrimination. Severely affected adults may also need psychotherapy to address the psychological and psychosocial difficulties related to having a chronic illness.

Other Psychosocial Interventions. For children, active intervention at school is essential to create a supportive, yet challenging, academic and social environment. Efforts to educate teachers, principals, and other students can result in increased awareness of TD and tolerance of the child’s symptoms.

Many young adults find TD support and social groups important for interpersonal contact and continued development. Efforts to keep people with TD working are important, as are rehabilitation efforts for those who are not working. Finding housing and obtaining disability or public assistance may be necessary for the most disabled patients with TD.

Perhaps the most useful educational intervention is to make the patient aware of the Tourette Syndrome Association, both national and local chapters. This and other self-help groups can be useful as a source of support and education for patients, families, and psychiatrists.

Genetic Counseling. One question commonly asked by young adults with TD is their risk for having a child with TD. Given the fact that many who present for clinical attention with TD have co-occurring conditions, genetic counseling of people with TS should include not only the risk for TD but also the risk for other neuropsychiatric problems such as ADHD or OCD. As the base rate of neuropsychiatric disorders is high, it is not uncommon for spouses of people with TD to also have a neuropsychiatric disorder. In providing counseling to these couples it is important that genetic counseling be conducted in regard to TD as well as other conditions that may be present in the young couple’s history.
Treatment of Co-occurring Psychiatric Disorders in TD

This section focuses on the special complexities of treating psychiatric disorders such as ADHD and OCD that commonly co-occur with TD. In general, the treatment approaches for ADHD and OCD are similar in patients with and without TD, with some notable differences. The details of the specific treatment approaches for ADHD and OCD in patients without co-occurring TD are addressed in separate chapters.

Treatment of ADHD

Nonpharmacological Approaches

The nonpharmacological approaches to ADHD in TD are similar to approaches in children without TD. The presence of a structured environment with consistent and positive behavioral management both at home and at school can produce significant improvement in ADHD symptoms. There are programs available for children with ADHD that include intensive and specific behavioral approaches. In spite of advances in nonpharmacological treatments, some families and psychiatrists, for a variety of reasons, find developing and implementing behavioral programs for children with ADHD difficult and do not take full advantage of the benefits of behavioral approaches.

Pharmacological Approaches

The major challenge in the treatment of ADHD in TD is the perceived risk of substantial tic exacerbations from the stimulant medication.

In the early 1970s, a number of reports of induction or exacerbation of tics by stimulant medications raised concerns that stimulants could be causing tics de novo or that increases in tic severity would endure even if stimulant medications were discontinued. Others noted, however, that tic induction or exacerbation was relatively infrequent and that the beneficial effects in some patients with TD outweighed any negative impact on tic severity (Law and Schachar 1999, Sanchez-Ramos and Weiner 1993).

Results of short and long-term controlled trials with stimulants in TD are positive and support a role for stimulants in patients with TD plus ADHD (Gadow et al. 1995, Gadow and Sverd 1990, The Tourette Syndrome Study Group 2002). In the most recent study, children with ADHD and a chronic tic disorder (N = 137) were randomly assigned to clonidine alone, methylphenidate alone, clonidine plus methylphenidate or placebo for the treatment of their ADHD. The results suggest that all the active treatments were superior to placebo with the combination treatment being the most effective. Moreover, the percentage of children with worsening of tics was similar across treatment conditions (20% for methylphenidate alone, 26% for clonidine alone, 22% for placebo), and tic severity lessened across all active treatment groups. Other side effects were predictable with sedation commonly associated with clonidine treatment (The Tourette Syndrome Study Group 2002). Given the controversy regarding the coadministration of clonidine and methylphenidate (Wilens et al. 1999) it is important to note the absence of cardiac side effects in children on combined medication.

Clonidine and Guanfacine

Clonidine and guanfacine are alpha-2 adrenergic agonists used for tic suppression and for ADHD alone and in combination with stimulants (The Tourette Syndrome Study Group 2002). Both clonidine and guanfacine have demonstrated efficacy for ADHD in TD (The Tourette Syndrome Study Group 2002; Scablil et al. 2001, respectively). Dosing of the alpha agonists for ADHD is similar to that for tic suppression and is described above.

Atomoxetine

Atomoxetine is a serotonin–norepinephrine reuptake inhibitor (SNRI) that has been demonstrated effective (Kratochvil et al. 2006) and is approved for the treatment of ADHD in children. Despite a handful of case studies showing an increase in tics on atomoxetine, a double-blind placebo controlled study of children and adolescents with ADHD and TD or CTD demonstrated that atomoxetine resulted
in reduction of both ADHD symptoms and tic severity (Allen et al. 2005). Atomoxetine is considered a safe and effective alternative to stimulants, and is more often prescribed over clonidine for youth with ADHD + tics (Johnston et al. 2006). Atomoxetine is dosed on a mg/kg/day basis or on a total daily dose basis for older teens and adults. Good ADHD control may take up to 4-6 weeks of treatment. Some clinicians combine atomoxetine and stimulants to improve overall ADHD control.

**Desipramine**

Desipramine is a tricyclic antidepressant with prominent noradrenergic activity that has been noted to improve attention and concentration in children and adolescents with TD plus ADHD (Spencer et al. 2002). Desipramine was superior to placebo in reducing inattention and hyperactivity/impulsivity (71% versus 0%) and motor and phonic tics (58% versus 5%). Symptom improvement is often significant with lower doses than needed for depression. Side effects are generally limited. The cardiac side effects of increased heart rate and elevation in blood pressure are usually not clinically significant (Wilens et al. 1993); however, reports of sudden death in children and adolescents (Riddle et al. 1993) have resulted in marked reductions nationally in the use of desipramine in this population.

**Nortriptyline**

Nortriptyline is another tricyclic antidepressant with some noradrenergic activity that has been used for the treatment of ADHD. A chart review of youth with ADHD + tics treated with nortriptyline documented moderate to marked improvement in both ADHD and tics (Wilens et al. 1993). Although the concern regarding sudden death is less with nortriptyline than with desipramine, it is prudent to obtain baseline and follow-up electrocardiograms.

**Bupropion**

Bupropion is often used for the treatment of ADHD in children given its long half-life and dopaminergic activity. There is little clinical data supporting its efficacy in ADHD or in ADHD with tics. Children may experience an exacerbation of tics on bupropion (Spencer et al. 1993), but caution is warranted regarding over-interpreting this finding given the lack of a controlled comparison with placebo in this report.

**Treatment of OCD**

**Nonpharmacological Approaches**

The positive role of cognitive–behavioral treatments of OCD is well established in children and adults. Three randomized controlled trials have emerged providing empirical support for the efficacy of cognitive–behavioral therapy (CBT) in youth (Barrett et al. 2004, de Haan et al. 1998, Pediatric OCD Treatment Study Team 2004), and CBT with exposure and response prevention is considered the standard of care for pediatric OCD (Franklin et al. 2002). Existing reports of children comorbid with OCD and tics show a poor response to SSRI monotherapy and suggest that CBT or CBT plus medication should be recommended for these youngsters (March et al. 2007). The only specific report of CBT or other nonpharmacological treatments of OCD in children with TD is a case study reporting success of exposure and response prevention in reducing tics and OCD symptoms (Woods et al. 2000). CBT for OCD and HRT for tics share the same conceptual framework and many of the same treatment elements. The use of these treatments in tandem for patients with TD and OCD may be useful.

**Pharmacological Treatments**

The number of agents available for the treatment of OCD in patients with and without TD is increasing. SSRIs (e.g., fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram) are recommended as the first line. Clomipramine, a tricyclic antidepressant, is often used and may be particularly useful when patients do not tolerate the SSRIs. The choice of serotonergic agent depends on the side effect profile, the potential drug interactions, and the psychiatrist’s familiarity with the drug. See Chapter 71 for a detailed description of pharmacological treatments for OCD. As the response to antiobsessional medications for patients with tics and OCD is less optimal compared to individuals with OCD alone (Geller et al. 2003, March et al. 2007), augmentation strategies with antipsychotics are recommended when patients have suboptimal response to initial treatment (McDougle et al. 1994, 2000).

The SSRIs have generally mild and somewhat similar side effect profiles. Despite the similarities among these medications, they are chemically different, especially in their metabolic pathway and patterns of drug interaction. The patterns of drug interaction are especially important because in children with complex presentations, multiple drugs are often used simultaneously. The potential for drug interactions with the SSRIs requires medication choices to be based on specific characteristics of the patient and the metabolic and drug interaction profile of the medication. Reports of a small increase in the potential for suicidal ideation and behavior while taking antidepressants has resulted in a warning in the product labeling for all antidepressants. For OCD the magnitude of the benefit outweighs this small risk (Bridge et al. 2007).

**Treatment-Refractory Cases**

Strategies for approaching two types of treatment-refractory symptoms are discussed here: (1) patients who are truly treatment-refractory, despite conventional and heroic treatments, and present with severe and impairing symptoms of TD and OCD and (2) patients, often children, who are clinically complex, enigmatic, and whose impairment is disproportionately greater than tic, obsessive–compulsive, or ADHD symptoms would suggest.

**Treatment-Refractory Tics**

Perhaps the most important “treatment” in patients with severe, incapacitating tics is a full clinical re-evaluation to assess the adequacy of previous evaluations and treatment efforts. Inadequate prior evaluations and treatment are not uncommon in treatment-refractory patients.

Three alternative treatment strategies are available for truly treatment-refractory tics. When a single tic or a few tics are refractory and impairing, the injection of botulinum toxin into the specific muscle group can be helpful. It is essential to collaborate with a neurologist experienced in using botulinum toxin (Jankovic 1994). This strategy is
most useful for painful, dystonic tics as well as those that are socially conspicuous and disabling. Botulinum toxin has a long duration of action, but the effect typically decreases 2–4 months post-injection; thus repeated injections may be necessary. Side effects are few, but may include excessive weakness in the affected muscle. Some patients reported a subsequent loss of premonitory urges following treatment.

There is a small and developing literature regarding the use of neurosurgical approaches to reduce tic severity. In the past 40 years, over 60 case reports have described ablative surgical approaches for reducing tic severity most often with limited success (Temel et al. 2004). As the exact pathophysiology of TS is unknown the surgical targets chosen have been based on conjecture and vary considerably. The patients described in these case series have invariably been severe, often suffering from significant co-occurring conditions and refractory to conventional treatments. At this time, there is little to no evidence, supporting the use of ablative surgical treatments for reducing tic severity.

More recently, there have been a small number of case reports describing the use of deep brain stimulation (DBS) for reducing tic severity (Neimat et al. 2006). DBS has been used successfully and is indicated for essential tremor, Parkinson's disease, some forms of epilepsy and more recently in dystonia, including childhood onset dystonia. Experimental uses have been reported in treatment refractory OCD (Greenberg et al. 2006) and depression (Mayberg et al. 2005). Although the actual number of reported TD cases has been few, media reports of “miraculous” outcomes have intensified the interest in this treatment modality. Much remains unknown about DBS for reducing tic severity including the mechanism by which brain stimulation reduces tic severity, the best target for stimulation, the optimum stimulation settings, the impact on co-occurring conditions, the minimum age for this approach and the potential for unusual behavioral side effects (Flaherty et al. 2005). As TD is often most severe in latency and early adolescence with improvement for the majority of patients in late teens and early 20s, it has been proposed that DBS be restricted to those in their mid-20s who have severe, persistent or worsening symptoms (Mink et al. 2006). Others have advocated that DBS should not be restricted from younger patients with severe TD who are significantly disabled, have been refractory to all forms of conventional treatment and are actively accumulating academic, occupational and social impairment. This is particularly true if the risks for neurosurgical side effects are known and can be included in the risk benefit ratio (Poyssky and Jimenez-Shahed 2007). At this time it is recommended that patients considering DBS for severe TD undergo this procedure at academic centers of excellence that include experts in the assessment and treatment of TD (neurology and psychiatry) as well as experienced neurosurgical teams (Mink et al. 2006).

**Treatment-Refractory OCD**

A similarly thorough and exhaustive re-evaluation is critical for patients with OCD and TD who present as treatment-refractory. Diagnostic re-evaluation focuses on considering all possible disabling psychiatric disorders and their hierarchical organization based on impairment.

Pharmacological re-evaluation is especially critical because there are an increasing number of new medications and potential medication combinations. Rather than repeatedly changing from one antipsychotic agent to another, consideration should be given to augmentation strategies. Augmentation often takes less time and may offer synergistic benefits. As noted above low-dose antipsychotic augmentation is the best first choice. Lithium and thyroid hormone are proven augmenters of antidepresants for depression, yet neither is proven as effective in OCD. Due to the frequent overlap of OCD and major depression, lithium or thyroid augmentation may be the next best choice especially if depression is prominent in the presentation. Lithium or thyroid hormone can be added to the SSRI or to the SSRI plus antipsychotic combination. Other augmenting agents are supported only by anecdotal evidence.

Treatment-refractory or malignant OCD has been the psychiatric disorder most frequently successfully treated with neurosurgical interventions in the modern era. Whereas it is a major treatment intervention, the surgical approaches are somewhat better defined, and the outcome in severe cases can be positive. Also, medical centers are available that specialize in the pre-surgical workup and the neurosurgical procedure (Mindus and Jenike 1992).

**Clinically Complex Patients**

Patients can become clinically complex when additional diagnoses are present or when otherwise straightforward treatments are challenging to implement. Patients may be significantly impaired and present diagnostic dilemmas even without severe tics or OCD symptoms.

**Diagnosis**

In clinically complex patients, the diagnostic challenge is not an accurate assessment of tics, ADHD, OCD symptoms, or LD, although this is important. For complex patients, the diagnostic goal is to identify the presence of other conditions or factors that may not be addressed by the current treatment or may actually be interfering with the current treatment approach. It is often undiagnosed psychiatric conditions (beyond TD, OCD, ADHD, and LD) that ultimately culminate in treatment failures (see Table 48–1).

**Treatment Implementation**

Psychiatrists with complex patients may consider altering their treatment approach to ensure comprehensive care. Developing a relationship with the patient and other major figures in the patient's life is necessary in order to appreciate the entire clinical picture and to effectively orchestrate treatment. Because it is increasingly difficult for the psychiatrist to be as involved as necessary, problems with poorly coordinated team efforts and the psychiatrist's lack of awareness of important clinical issues can have a negative impact on the treatment of a patient.

Experience in tertiary care centers suggests that expanded time with the parents is a critically important approach to care. Psychiatrists who form a treatment partnership with families, respecting and addressing their concerns, educating them about TD, training them to evaluate and manage complex behaviors, and empowering them to be an effective advocate for their child, are providing optimal care. In working directly with families, the collection of important information regarding the family's and patient’s functioning is direct and regular, and often small, but...
targeted interventions can produce changes in family functioning that have a positive ripple effect throughout the lifetime of the child. Although focusing on the family will not make all complex patients with TD easier to treat, less than adequate contact will certainly create barriers to clinical care.

Pharmacological Treatment Dilemmas

It is often difficult to get accurate information from young patients regarding treatment response and side effects. Children, parents, and psychiatrists, despite adequate collaboration, may differentially conceptualize target symptoms, side effect profiles, and what constitutes a positive clinical response. Reporting bias as a result of ambiguity makes all but the most robust clinical responses difficult to observe. A lack of a clinical response in complex patients may be related to inadequately monitoring medication effects and/or inadequate treatment trials (Walkup 1995).

Clinically complex patients may not respond robustly to a particular medication and may require multiple medication trials to identify medications or combinations that offer maximal benefit. Sequential treatment trials are difficult for children and families looking for a single powerful intervention. However, optimal benefit in clinically complex patients usually requires sequential trials, medication combinations, and combined medication and psychosocial interventions. Increased treatment complexity can result in an added risk of confusion, which is minimized by an excellent communication among patient–family–psychiatrist.

For psychiatrists, the continued proliferation of psychotropic medications can result in less expertise regarding the range of medication-specific clinical effects and side effects. In clinically complex patients, the prescription of unfamiliar medications may be necessary but may add to the risk that a trial will be discontinued prematurely because of doubt about a side effect. In addition, unusual side effects such as apathy or disinhibition syndromes (Hoehn-Saric et al. 1990, 1991) seen in some patients receiving specific SSRIs, may go unnoticed and add to clinical morbidity.

Pharmacological interventions offer great promise for treating TD. However, clinical experience suggests that building excellent diagnostic skills, creating relationships with the patient and family, and developing a keen eye for effects and side effects are necessary for benefits to be maximized. Less intensive efforts may make patients appear more complex than necessary.

Conclusion

TD and the other tic disorders are model neuropsychiatric disorders with childhood onset. Many of the research efforts in the clinical and basic science of TD, outlined in this chapter, have set a standard for research efforts in other childhood neuropsychiatric disorders. Future research efforts will continue to focus on identifying the basic genetic and neurobiological mechanisms in TD as well as the complex prevention and rehabilitation efforts necessary to minimize morbidity and maximize long-term functioning.

disorder (OCD) and Tourette’s syndrome (TS). The International Journal of Neuropsychopharmacology 9(1), 95–100.

Enuresis

**Definition**
Functional enuresis is usually defined as the intentional or involuntary passage of urine into bed or clothes in the absence of any identified physical abnormality in children older than 4 years of age (see the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR), criteria for enuresis). Although there is no good evidence that the condition is primarily psychogenic, it is often associated with a psychiatric disorder, and enuretic children are frequently referred to mental health services for treatment.

**Course and Natural History**
The acquisition of urinary continence at night is the end stage of a fairly consistent developmental sequence. Bowel control during sleep marks the beginning of this process and is followed by bowel control during waking hours. Bladder control during the day occurs soon after and finally, after a variable interval, nighttime bladder control is achieved. Most children achieve this final stage by the age of 36 months. With increasing age, the likelihood of spontaneous recovery from enuresis becomes less (Oppel et al. 1968), so that, for instance, 40% of 2-year-olds with enuresis become dry in the next year and 20% of enuretic 3-year-olds become dry before age 4 years, but only 6% of enuretic 4-year-olds become dry in the following year. The chronic nature of the condition is further shown in the study by Rutter et al. (1973), in which only 1.5% of 5-year-old bed wetters became dry during the next 2 years. In a recent epidemiologic study, at 7.5 years, 15.5% of children were found to still wet the bed, but most wet once a week or less. Only 2.6% met DSM-IV-TR criteria of Nocturnal Enuresis (wetting at least twice a week). Both daytime wetting and bed-wetting was found in 3.3% of children, with 2.3% having both daytime soiling and bed-wetting (Butler et al. 2005).

Nocturnal enuresis is as common in boys as girls until the age of 5 years, but by age 11 years, boys outnumber girls 2:1 (Oppel et al. 1968, Rutter et al. 1973, Essen and Peckham 1976). Not until the age of 8 years do boys achieve the same levels of nighttime continence that are seen in girls by the age of 5 years (Verhulst et al. 1985). This appears to be due to the slower physiological maturation in boys. In addition, the increased incidence of secondary enuresis (occurring after an initial 1-year period of acquired continence) in boys further affects the sex ratio seen in later childhood. Daytime enuresis occurs more commonly in girls (Blomfield and Douglas 1956, Hallgren 1956, Jarvelin et al. 1988) and is associated with higher rates of psychiatric disturbance (Rutter et al. 1973). Recent approaches to classification (Butler et al. 2006) have strayed from the primary/secondary distinction in favor of...

**DSM-IV-TR Criteria**

Enuresis (Not Due to a Medical Condition)

A. Repeated voiding of urine into bed or clothes (whether involuntary or intentional).

B. The behavior is clinically significant as manifested by either a frequency of twice a week for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.

C. Chronological age is at least 5 years (or equivalent developmental level).

D. The behavior is not due exclusively to the direct physiological effect of a substance (e.g., a diuretic) or a general medical condition (e.g., diabetes, spina bifida, a seizure disorder).

Specify type:

- **Nocturnal only**: passage of urine only during nighttime sleep
- **Diurnal only**: passage of urine during waking hours
- **Nocturnal and diurnal**: a combination of the two subtypes above

Etiology and Pathophysiology

Identifying a cause for enuresis is not a simple task despite numerous descriptions of correlations or associations between enuresis and a wide variety of biological and psychosocial factors. It has been suggested (Butler and Holland 2000) that there are 3 processes that alone or in combination can engender various forms of enuresis: (1) lack of arginine vasopressin release during sleep (which would normally decrease urine production), (2) overactivity of the bladder (uninhibited bladder contractions) or low functional bladder capacity (e.g., volume of urine voided after the child has postponed urination for as long as possible), and (3) inability of the child to wake up in response to sensations of a full bladder.

Biological factors described include a structural pathological condition or infection of the urinary tract (or both), low functional bladder capacity, abnormal antidiuretic hormone (ADH) secretion, abnormal depth of sleep, genetic predisposition, and developmental delay. Evidence has also been found for sympathetic hyperactivity (Dundaroz et al. 2001a) and delayed organ maturation as seen by delay in ossification (Dundaroz et al. 2001b). Touchette et al. (2005) have demonstrated an association between enuresis and developmental delay with impaired acquisition of gross motor (sitting/crawling) and language milestones in future bed-wetters.

Obstructive lesions of the urinary outflow tract, which can cause urinary tract infection (UTI) as well as enuresis, have been thought to be important, with a high prevalence of such abnormalities seen in enuretic children referred to urologic clinics (Cohen 1975). This degree of association is not seen at less specialized pediatric centers, however, and most studies linking urinary outflow obstruction to enuresis are methodologically flawed (Shaffer et al. 1979). Structural causes for enuresis should be considered the exception rather than the rule (Sorotzkin 1984).

The association between UTI and enuresis has been demonstrated in two main ways. UTI has been found to occur frequently in children, especially girls, and a large proportion (85%) of them have been shown to have nocturnal enuresis (Savage et al. 1969). Also, in 10% of bed-wetting girls, urinalysis results show evidence of bacterial infection (Dodge et al. 1970). The consensus is that treating the infection rarely stops the bed-wetting; UTI is probably a result rather than a cause of enuresis (Forsythe and Redmond 1974).

The concept that children with enuresis have low functional bladder capacities has been widely promoted (Starfield 1967). Shaffer et al. (1984) found a functional bladder capacity one standard deviation lower than expected in 55% of a sample of enuretic children in school clinics. Although low functional capacity may predispose the child to enuresis, successful behavioral treatment does not appear to increase that capacity. It seems rather that in treated individuals, the sensation of a full (small) bladder promotes waking to pass urine so that enuresis does not occur (Fielding 1980). Reduction of nocturnal secretion of ADH has been described in a small number of children with enuresis (Norgaard et al. 1985, Rittig et al. 1989). This deficiency may produce excessive amounts of dilute urine during the night and overwhelming bladder capacity causing enuresis. Several mechanisms are associated with enuresis including increased nocturnal urine volume, small nocturnal functional bladder capacity, increased spontaneous bladder contractions, and the inability to arouse to the stimulus of a large and/or contracting bladder. This may identify two main groups of children with enuresis—those who demonstrate nocturnal spontaneous bladder contractions (detrusor dependent enuresis) and those with nocturnal polyuria (volume dependent enuresis).

It is widely believed by parents that children who have enuresis at night sleep more deeply and are especially difficult to wake. This subjective opinion was not supported by Boyd’s study (1960), comparing the time it took to awaken normal children and children with enuresis. Furthermore, enuresis had been shown to occur randomly with regard to stage of sleep, and any relationship is due to the amount of time spent in that stage (Mikkelsen and Rapoport 1980). A recent study (Wolflish 2001), however, has shown that children with enuresis were difficult to arouse in the first two-thirds of the night, which was also seen to be associated with the period of greatest wetting frequency. In addition, a study (Hunsballe 2000) looking at EEG power analysis showed that enuretics had a significant increase in the EEG delta power component during baseline sleep compared with controls, whereas no difference was detected with conventional polysomnographic techniques.

The evidence for some genetic predisposition is strong. Approximately 70% of children with nocturnal enuresis
have a first-degree relative who also has or has had nocturnal enuresis (Bakwin 1961). Twin studies have shown greater monozygotic (68%) than dizygotic (36%) concordance (Bakwin 1971). An association between enuresis and early delays in motor, language, and social development has been noted in both prospective community samples (Essen and Peckham 1976, Ferguson et al. 1986) and a large retrospective study of clinical subjects (Steinhausen and Gobel 1989).

Genetic factors are probably the most important in the etiology of nocturnal enuresis but somatic and psychosocial environmental factors have a major modulatory effect. Most commonly, nocturnal enuresis is inherited via an autosomal dominant mode of transmission with high penetrance (90%). However, a third of all cases are sporadic, and the difference between sporadic and familial forms is not known. Four gene loci associated with nocturnal enuresis have been identified but the existence of others is presumed (locus heterogeneity) (von Gontard et al. 2001). Many psychosocial correlates have also been described, including delayed toilet training, low socioeconomic class, stress events, and other child psychiatric disorders. Prospective studies from New Zealand (Ferguson et al. 1986) and from kibbutz-raised children in Israel (Kaufman 1962) suggest that higher rates of enuresis are seen in children in whom toilet training is delayed until after the age of 18 months. The data on social class and enuresis are unclear. Early reports (Oppel et al. 1968, Rutter et al. 1973) linked various indices of social disadvantage to increased prevalence of enuresis, however, multivariate studies (Ferguson et al. 1986) failed to demonstrate a relationship between primary enuresis and psychosocial disadvantage or social class, or both. Stress events seem to be more clearly associated with secondary enuresis. Reported events include the birth of a younger sibling (Werry and Cohrssen 1965), early hospitalizations, (Douglas 1973), and head injury (Chadwick 1985).

Psychiatric disorder occurs more frequently in enuretic children than in other children. The relative frequency of disorder ranges from two to six times that in the general population and is more frequent in girls, in children who also have diurnal enuresis, and in children with secondary enuresis (Rutter et al. 1973, Essen and Peckham 1976). There have been no specific types of psychiatric disorder identified in children with enuresis (Mikkelsen and Rapoport 1980).

There is little evidence that enuresis is a symptom of underlying disorder because psychotherapy is ineffective in reducing enuresis (Werry and Cohrssen 1965), anxiolytic drugs have no antinuerectic effect, tricyclic antidepressants exert their therapeutic effect independent of the child’s mood (Blackwell and Currah 1973), and purely symptomatic therapies, such as the bell and pad, are equally effective in disturbed and nondisturbed children (Young and Baker 1973).

A further explanation for the association is that enuresis, a distressing and stigmatizing affliction, may cause the psychiatric disorder. However, although some studies have shown that enuretic children who undergo treatment become happier and have greater self-esteem (Behrl et al. 1956, Baker 1969), other studies show that psychiatric symptoms do not appear to lessen in children who are successful with a night alarm (Shaffer et al. 1984, Moffat et al. 1987).

A final possibility is that enuresis and psychiatric disorder are both the result of joint etiological factors such as low socioeconomic status, institutional care, large sibships, parental delinquency, and early and repeated disruptions of maternal care (Rutter et al. 1973, Essen and Peckham 1976, Miller et al. 1960). Shared biological factors may also be important in that delayed motor, speech, and pubertal development, already shown to be associated with enuresis, have proven to be more frequent in disturbed enuretic children than in those without psychiatric disorder.

**Diagnosis and Differential Diagnosis**

The presence or absence of conditions often seen in association with enuresis, such as developmental delay, UTI, constipation, and comorbid psychiatric disorder, should be assessed and ruled out as appropriate (Figure 49–1). Other causes of nocturnal incontinence should be excluded, for example, those leading to polyuria (diabetes mellitus, renal disease, diabetes insipidus) and, rarely, nocturnal epilepsy.

**Assessment**

**History**

Information on the frequency, periodicity, and duration of symptoms is needed to make the diagnosis and distinguish functional enuresis from sporadic seizure-associated enuresis. If there is diurnal enuresis, an additional treatment plan is required. A family history of enuresis increases the likelihood of a diagnosis of functional enuresis and may explain a later age at which children are presented for treatment. Projective identification by the affected parent—whereby the parent does not separate feelings about himself having the diagnosis and the current experience of the affected child—may further hinder treatment. For subjects with secondary enuresis, precipitating factors should be elicited, although such efforts often represent an attempt to assign meaning after the event.

Questions that are useful in obtaining information for treatment planning include “Why is this a problem?” and “Why does this need treatment now?” because these factors may influence the choice of treatment (is a rapid effect needed?) or point to other pressures or restrictions on therapy. It is important to inquire about previous management strategies—for example, fluid restriction, nightlifting (getting the child out of bed to take them to the toilet in an often semi-asleep state), rewards, and punishments—used at home. Parents often come with the assertion that they have tried everything and that nothing has helped. Examining the reasons for failure of simple strategies is useful for ensuring that more sophisticated treatments do not fail the same fate. There is little evidence that fluid restriction is useful, although nightlifting may be beneficial for the large number of children who never reach professional attention. Rewards are usually material and are given only for unreasonably high performance levels, with the delay between action and reward being too long. Physical punishment and verbal chastisements, ineffective at best, may well maintain the enuresis. Punishment is often too harsh and tends to be applied inconsistently depending on parental mood. If specific treatments have been prescribed, either behavioral or pharmacological, it is
important to discover the reasons they may have failed, for example, parental discord, noncompliance, or relapse after an initial response.

**Mental Status Examination**
The child's views and any misconceptions that he or she may have about the enuresis, its causes, and its treatment should be fully explored. Asking the child for three wishes may help determine whether the enuresis is a concern to the child. This may unmask marked embarrassment or guilt from behind a facade of denial about the problem and can be educational for parents who believe their children could stop wetting “if only they wanted to or tried harder.” Pictures drawn by the child that describe how the child views himself or herself when enuresis is a problem and when it is not is appropriate for younger children and can graphically illustrate the misery experienced by children with enuresis.

**Physical Examination**
All children should have a routine physical examination, with particular emphasis placed on detection of congenital malformations, which are possibly indicative of urogenital abnormalities. A midstream specimen of urine should be examined for the presence of infection. Radiological or further medical investigation is indicated only in the presence of infected urine, enuresis with symptoms suggestive of recurrent UTI (frequency, urgency, and dysuria), or polyuria.

**Treatment**
Practical management for nocturnal enuresis is presented in Table 49–1. Studies suggest that only a minority of children with enuresis are ever assessed and treated (Miller et al. 1960, Foxman et al. 1986) and that many of those who are referred do not receive adequate treatment. Many families, and clinicians, seem to accept bed-wetting as part of normal childhood.

The overall goals of treatment can depend on the reason for referral. Commonly, the child is brought to the physician before some planned activity, for example, a family vacation or a trip to camp, and the need is for a rapid (e.g., pharmacological) short-term therapy. A gradual behavioral approach would not likely meet with much approval even though it may offer a chance for a permanent cessation of wetting.

**Standard Treatment**
About 10% of children have a reduction in the number of wet nights after a single visit to a clinician in which the only intervention was the recording of baseline wetting frequency and simple reassurance (Shaffer et al. 1968). Such reassurance should make clear that enuresis is a biological condition that is made worse by stress and that may be associated in a noncausal way with other psychiatric disorders. Younger children can be told that their problem is shared by many others of the same age. The excellent prognosis for patients who comply with therapy should be stressed. Recording the frequency of enuresis can be achieved by using a simple star chart. This is most effective if performed by the child, who records each dry night with a star. The completed chart is then shown to the parents on a daily basis, and they can provide appropriate praise and reinforcement.

Waking and Fluid Restriction

Although systematic studies have failed to show any effect of these interventions with enuretic inpatients, it may be that waking and fluid restriction work for the majority of enuretic children who are not referred for treatment. If waking does appear to reduce the number of wet nights from baseline, a more systematic application may be indicated.

Surgery

Based on the premise that enuresis is causally associated with outflow tract obstruction, various surgical procedures have been advocated, for example, urethral dilatation, meatalotomy, cystoplasty, and bladder neck repair (Mahoney 1971). This cannot be supported because, in addition to the dubious concept of outflow tract obstruction per se, the surgery does not alter the urodynamics of the bladder. Reported positive treatment effects are slight (no controlled studies exist), and there remains a significant potential for adverse effects (urinary incontinence, epididymitis, and aspermia).

Pharmacotherapy

Although it has been repeatedly demonstrated that temporary suppression rather than cure of enuresis is the usual outcome of drug therapy, it remains the most widely prescribed treatment in the US (Foxman et al. 1986). Four classes of drugs have principally been employed: synthetic AHDs, tricyclic antidepressants, stimulants, and anticholinergic agents.

Synthetic ADH. A number of randomized double-blind placebo-controlled trials have shown that the synthetic vasopressin DDAVP (desmopressin) is effective in the treatment of enuresis (Dimson 1986, Miller and Klauber 1990). The drug is usually administered intranasally, although oral preparations of equal efficacy have been developed (equivalent oral dose is 10 times the intranasal dose). It has been shown (Miller et al. 1989) that almost 50% of children are able to stop wetting completely with a single nightly dose of 20–40 μg of DDAVP given intranasally. A further 40% are afforded a significant reduction in the frequency of enuresis with this treatment. As with tricyclic antidepressants, however, when treatment is stopped, the vast majority of individuals relapse (Leebeek-Groenewegen et al. 2001). A meta-analysis (Glazener and Evans, 2002) showed that desmopressin (20 μg) was more effective than placebo with 1.34 fewer wet nights per week but that only 20% of treated subjects achieved dryness (2% placebo). Side effects of this medication include nasal pain and congestion, headache, nausea, and abdominal pain. Serious problems of hyponatremic hypovolemia leading to seizures are rare, but should be considered if young children show the prodromal symptoms (nausea, vomiting and headache) during initiation of DDAVP therapy (Thumfart et al. 2005). Prevention of excessive water intake (not greater than 240 mL (8oz) after nighttime administration of desmopressin is advisable. It is also important to be aware that intranasal absorption is reduced when the patient has a cold or allergic rhinitis. The mode of action of desmopressin is unknown. It may reduce the production of nighttime urine to an amount less than the (low) functional volume of the enuretic bladder, thereby eliminating the urge to micturate. It is uncertain whether desmopressin administration is correcting a natural deficiency of vasopressin or is exerting a true pharmacological effect. With regard to identifying those most likely to respond to DDAVP treatment, it has been found (Kruse et al. 2001) that those most likely to be permanently dry are older children who respond to lower dose (20 μg) desmopressin and who do not wet frequently.

Tricyclic Antidepressants. The short-term effectiveness of imipramine and other related antidepressants has also been demonstrated via many randomized double-blind, placebo-controlled trials (Shaffer et al. 1968, Rapoport et al. 1980, Simeon et al. 1981). Imipramine reduces the frequency of enuresis in about 85% of bed wetters and eliminates enuresis in about 30% of these individuals. Nighttime doses of 1–2.5 mg/kg are usually effective (Jorgensen et al. 1980), and a therapeutic effect is usually evident in the first week of treatment. Relapse after withdrawal of medication is almost inevitable, so that 3 months after the cessation of tricyclic antidepressants, nearly all patients will again have
enuresis at pretreatment levels (Shaffer et al. 1968). Side effects are common and include dry mouth, dizziness, postural hypotension, headache, and constipation. Toxicity after accidental ingestion or overdose is a serious consideration, causing cardiac effects, including arrhythmias and conduction defects, convulsions, hallucinations, and ataxia. Concern has been expressed about the possibility of sudden death (presumably caused by arrhythmia) in children taking tricyclic drugs. The mode of action for tricyclic antidepressants is unclear. It does not appear to depend on their antidepressant properties because response is unrelated to the presence or absence of mood symptoms. One observation is that tricyclic agents seem to increase functional bladder volumes (Shaffer et al. 1979), possibly resulting from noradrenergic reuptake inhibition (Rapoport et al. 1980).

**Stimulant Medication.** Sympathomimetic stimulants such as dexamethasone, oxybutynin, and terodiline can reduce the frequency of voiding in individuals with neurogenic bladders, reduce urgency, and increase functional bladder capacity. There is no evidence, however, that these anticholinergic drugs are effective in bed-wetting, although they may have a role in diurnal enuresis (Wallace and Forsythe 1969, Elmer et al. 1988). Side effects are frequent and include dry mouth, blurred vision, headache, nausea, and constipation (Baigrie et al. 1988).

**Anticholinergic Drugs.** Drugs such as propantheline, oxybutynin, and terodiline can reduce the frequency of voiding in individuals with neurogenic bladders, reduce urgency, and increase functional bladder capacity. There is no evidence, however, that these anticholinergic drugs are effective in bed-wetting, although they may have a role in diurnal enuresis (Wallace and Forsythe 1969, Elmer et al. 1988). Side effects are frequent and include dry mouth, blurred vision, headache, nausea, and constipation (Baigrie et al. 1988).

**Psychosocial Treatments**

The night alarm, originally developed by Pfaundler (1904), was first used in children with enuresis by Mowrer and Mower (1938). This system used two electrodes separated by a device (e.g., bedding) connected to an alarm. When the child wet the bed, the urine completed the electrical circuit, sounded the alarm, and the child awoke. All current night alarm systems are merely refinements on this original design. A vibrating pad beneath the pillow can be used instead of a bell or buzzer, or the electrodes can be incorporated into a single unit or can be miniaturized so that they can be attached to night (or day) clothing. With treatment, full cessation of enuresis can be expected in 80% of cases. Reported cure rates (defined as a minimum of 14 consecutive dry nights) have ranged from 50–100% (Forsythe and Butler 1989, Butler 1991).

The problem with this form of enuretic treatment, however, is that cure is usually achieved only within the second month of treatment (Kolvin et al. 1972). This factor may influence clinicians to prescribe pharmacological treatments that, although more immediately gratifying, do not offer any real prospect of cure. It has been suggested that adjuvant therapy with methamphetamine (Young and Turner 1965) or desmopressin (Bolland and Nettlebeck 1981) will reduce the amount of time before continence is achieved. Using a louder auditory stimulus (Finley and Wansley 1977) or using the body-worn alarm (Butler et al. 1990) may also improve the speed of treatment response. Factors associated with delayed acquisition of continence include failure of the child to wake with the alarm, maternal anxiety, and a disturbed home environment, although no influence has been seen regarding the age of the child or the initial wetting frequency (Young and Morgan 1973, Dische et al. 1983).

A further consequence of the delayed response to a night alarm is that families fail to persist with treatment and may abandon the treatment too soon. Premature termination can occur in as many as 48% of cases (Turner et al. 1970) and is more common in families that have made little previous effort to treat the problem, in families that are negative or intolerant of bed-wetting, and in children who have other behavioral problems (Wagner and Johnson 1988). Aspects of treatment that may also reduce compliance with the alarm include failure to understand or follow the instructions, failure of the child to awaken, and frequent false alarms (Turner et al. 1970). The only reported side effect of treatment with the night alarm is “buzzer ulcers” caused by the child lying in a pool of ionized urine. This problem has been eliminated with modern transistorized alarms that do not employ a continuous, relatively high voltage across the electrodes to detect enuresis (Malem et al. 1982).

Relapse after successful treatment, if it occurs, will usually take place within the first 6 months after cessation of treatment. It is reported that approximately one-third of children relapse (Doleys et al. 1977), however, no clear predictors of relapse have been identified (Fielding 1985). Strategies aimed at reducing relapse rates, such as overlearning (Houts et al. 1984) or intermittent reinforcement paradigms (Finley et al. 1973), have not been demonstrated to be of clinical value (Forsythe and Butler 1989). A recent review (Butler and Gasson 2005) of alarm treatment that combined 20 studies meeting quality criteria, reported that an overall 65% success (>14 successive dry nights) rate was seen, with 42% relapsing following cessation of treatment. Improved success was seen in studies that emphasized behavioral reinforcement of rapid waking to the alarm and was thought more appropriate for those with mono-symptomatic nocturnal enuresis (e.g., absence of daytime frequency and urgency).

The mode of action of the night alarm can be explained using theories of classical or operant conditioning. In classical conditioning, bladder distention or a sense of the need to pass urine becomes associated with the auditory signal, leading to the conditioned response of waking. Operant conditioning theories would view the alarm as a punishment to be avoided and may explain why individuals still become dry when the alarm is placed in the bed but is not switched on (Deleon and Mandell 1966). Social learning is also important because the night alarm and associated systematic recording may help the family focus on dry nights and provide contingent rewards (praise) for rapid response to the auditory signal. Successful treatment with the nighttime alarm results in reduced nocturnal urine volume, possibly mediated by increased production of arginine vasopressin (Oresdsson and Jorgensen 1998). Table 49–2 presents various remedies for night alarm problems.

**Dry Bed Technique.** An elaborate collection of interventions has been designed by Azrin et al. (1974) and includes high fluid intake (an attempt at “over-learning”), retention

*Summary*

In the last 30 years, there have been approximately 50 randomized trials conducted, involving over 3,500 children treated pharmacologically or behaviorally for primary nocturnal enuresis. The quality of many of these trials is poor with very few trials comparing drugs with each other, or drugs versus, or combined with alarms or other behavioral interventions, and few having adequate follow-up periods. Desmopressin and tricyclics appeared equally effective while on treatment, but this effect was not sustained after treatment stopped. It is clear that further comparisons between drug and behavioral treatments are needed, and should include relapse rates after treatment is finished.

*Assessment and Management of Diurnal Enuresis*

Daytime enuresis, although it can occur together with nighttime enuresis, has a different pattern of associations and responds to different methods of treatment. It is much more likely to be associated with urinary tract abnormalities, including UTI, and to be comorbid with other psychiatric disorders. As a result, a more detailed and focused medical and psychiatric evaluation is indicated. Urine should be checked repeatedly for infection, and the threshold for ordering ultrasonographical visualization of the urological system should be low. The history may make it apparent that the daytime wetting is situation specific. For example, school-based enuresis in a child who is too timid to ask to use the bathroom could be alleviated by the teacher's tactfully reminding the child to go to the bathroom at regular intervals.

Observation of children with diurnal enuresis (Fielding et al. 1978) has established that they do experience an urge to pass urine before micturition but that either this urge is ignored or the warning comes too late to be of any use because of an “irritable bladder.” Therefore, treatment strategies are based on establishing a pattern of toileting before the times that diurnal enuresis is likely to occur (usually between 12 noon and 5 pm) and using positive reinforcement to promote regular use of the bathroom (Berg et al. 1982).

Portable systems that can be worn on the body and use a sensor in the underwear as well as an alarm that can be worn on the wrist have been developed. Halliday et al. (1987) studied two versions of this apparatus—one in which the alarm sounding was contingent on the sensor’s detecting wetness in the underwear, and another in which the alarm was merely worn on the wrist and went off at predetermined intervals. Interestingly, success rates (two-thirds of children were cured and mostly maintained continence for a full 2-year follow-up period) showed no significant differences between the wetness alarm and the simple timed alarm. A simple therapeutic alternative, therefore, is to buy the child a digital watch with a countdown alarm timer.

Unlike nocturnal enuresis, drug treatment with tricyclic antidepressants such as imipramine is ineffective (Meadow and Berg 1982), whereas the use of anticholinergic agents such as oxybutynin and terodiline shows a therapeutic impact on the frequency of daytime enuresis (Baigrie et al. 1988, Pfaundler 1904).

control training, training the child to awaken rapidly (using a nighttime alarm), and rapid reinforcement for correct daytime micturition. Without the use of a night alarm, the program produces no better effects than no treatment at all (Nettlebeck and Langeluddecke 1979). In view of the intensive effort needed by the family and adverse effects on pre-school children, such as increased temper tantrums or social withdrawal (Mattsson and Ollendick 1977), the value of the dry bed technique remains questionable.

**Ultrasonic Bladder Volume Alarm**

Although the traditional enuresis alarm has good potential for a permanent cure, the child is mostly wet during treatment. Furthermore, the moisture alarm requires that the child make the somewhat remote association between the alarm event and a full bladder after the bladder has emptied. In an exploratory study (Pretlow 1999), a new approach to treating nocturnal enuresis was investigated using a miniature bladder volume measurement instrument during sleep. An alarm sounded when bladder volume reached 80% of the typical enuretic volume. Two groups were studied. Group 1 used the nighttime device alone; Group 2, in addition, had supplementary daytime bladder retention training (aiming to increase functional capacity). In Groups 1 and 2, the mean dryness rate before study initiation versus during the study was 32.9 and 9.3% versus 88.7 and 82.1%, respectively. Nighttime bladder capacity increased 69% in Group 1 and 78% in Group 2, while the cure rate was 55% (mean treatment period 10.5 months) and 60% (mean treatment period 7.2 months), respectively. On this data, bladder volume tracking seems to be a promising treatment for nocturnal enuresis in that it prevents the enuretic event, appears to facilitate a permanent cure, and is noninvasive.

**Acupuncture.** The efficacy of traditional Chinese acupuncture has been studied (Serel et al. 2001) in a small (n = 50) clinical sample. It was reported that within 6 months, 86% of patients were completely dry and a further 10% of patients were dry on at least 80% of nights. Relapse rates appeared better than with psychopharmacologic agents.

**Summary**

In the last 30 years, there have been approximately 50 randomized trials conducted, involving over 3,500 children treated pharmacologically or behaviorally for primary nocturnal enuresis. The quality of many of these trials is poor with very few trials comparing drugs with each other, or drugs versus, or combined with alarms or other behavioral interventions, and few having adequate follow-up periods. Desmopressin and tricyclics appeared equally effective while on treatment, but this effect was not sustained after treatment stopped. It is clear that further comparisons between drug and behavioral treatments are needed, and should include relapse rates after treatment is finished.

*Assessment and Management of Diurnal Enuresis*

Daytime enuresis, although it can occur together with nighttime enuresis, has a different pattern of associations and responds to different methods of treatment. It is much more likely to be associated with urinary tract abnormalities, including UTI, and to be comorbid with other psychiatric disorders. As a result, a more detailed and focused medical and psychiatric evaluation is indicated. The history may make it apparent that the daytime wetting is situation specific. For example, school-based enuresis in a child who is too timid to ask to use the bathroom could be alleviated by the teacher’s tactfully reminding the child to go to the bathroom at regular intervals.

Observation of children with diurnal enuresis (Fielding et al. 1978) has established that they do experience an urge to pass urine before micturition but that either this urge is ignored or the warning comes too late to be of any use because of an “irritable bladder.” Therefore, treatment strategies are based on establishing a pattern of toileting before the times that diurnal enuresis is likely to occur (usually between 12 noon and 5 pm) and using positive reinforcement to promote regular use of the bathroom (Berg et al. 1982).

Portable systems that can be worn on the body and use a sensor in the underwear as well as an alarm that can be worn on the wrist have been developed. Halliday et al. (1987) studied two versions of this apparatus—one in which the alarm sounding was contingent on the sensor’s detecting wetness in the underwear, and another in which the alarm was merely worn on the wrist and went off at predetermined intervals. Interestingly, success rates (two-thirds of children were cured and mostly maintained continence for a full 2-year follow-up period) showed no significant differences between the wetness alarm and the simple timed alarm. A simple therapeutic alternative, therefore, is to buy the child a digital watch with a countdown alarm timer.

Unlike nocturnal enuresis, drug treatment with tricyclic antidepressants such as imipramine is ineffective (Meadow and Berg 1982), whereas the use of anticholinergic agents such as oxybutynin and terodiline shows a therapeutic impact on the frequency of daytime enuresis (Baigrie et al. 1988, Pfaundler 1904).
The age cutoff for "normality" is set at 4 years, the age at which 95% of children have acquired fecal continence (Stein and Susser 1967). As with urinary continence, girls achieve bowel control earlier than boys.

**Encopresis**

**Definition**

Encopresis is usually defined as the intentional or involuntary passage of stool into inappropriate places (e.g., clothing or floor) whether involuntary or intentional.

**Course and Natural History**

Less than one-third of children in the US have completed toilet training by the age of 2 years (Steubens and Silber 1974), with a mean age of 27.7 months (Brazelton 1962). Bowel control is usually achieved before bladder control.

**Epidemiology**

The overall prevalence of encopresis in 7- and 8-year-old children has been shown to be 1.5%, with boys (2.3%) affected more commonly than girls (0.7%). There was a steadily rising likelihood of continence with increasing age, until by age 16 years the reported prevalence was almost zero (Bellman 1966). Rutter and coworkers (1970) reported a rate of 1% in 10- to 12-year-old children, with a strong (5:1) male/female ratio. Retrospective study of clinic-referred encopretic children has shown that 40% of cases are primary (true failure to gain control), with a mean age of 6.7 years, and 60% of cases are secondary, with a mean age of 8 years (Levine 1975). Eighty percent of patients were constipated, with no difference in this feature seen between primary and secondary subtypes.

**Etiology and Pathophysiology**

No clear single causative pathway has been established. The constipated–nonconstipated distinction does, however, generate some specificity in terms of associations that may be important etiologically. Within the first year of life, children can show a tendency toward constipation (Levine 1982), with concordance for constipation being six times more frequent in monozygotic than in dizygotic twins (Bakwin 1971). Fecal retention and reduced stool frequency between
12 and 24 months of age can predict later encopresis (Levine 1975). Encopretic children with constipation and overflow are found to have rectal and colonic distention, massive impaction with hard feces, and a number of specific abnormalities of anorectal physiology. These abnormalities, which may be primary or secondary to constipation, include elevated anal resting tone, decreased anorectal motility and weakness of the internal anal sphincter (Loening-Baucke and Younoszai 1982), and dysfunction of the external anal sphincter, for example, contraction during defecation (Wald et al. 1986, Loening-Baucke et al. 1987).

Encopresis may occur after an acute episode of constipation following illness or a change in diet (Pettei and Davidson 1988). In addition to the pain and discomfort caused by attempts to pass an extremely hard stool, a number of specific painful perianal conditions such as anal fissure can lead to stool withholding and later fecal soiling. Stressful events such as the birth of a sibling or attending a new school have been associated with up to 25% of cases of secondary encopresis (Levine 1975). In nonretentive encopresis, the main theories center on faulty toilet training. Stress during the training period, coercive toileting leading to anxiety and “pot phobia,” and failure to learn or to have been taught the appropriate behavior (Anthony 1957, Berg and Jones 1964) have all been implicated. True fecal urgency, which may have a physiological or pathological basis, may also be important in a small proportion of cases (Woodmansey 1967).

It has been asserted that primary encopresis is more common in children from lower socioeconomic class families who received neglectful toilet training (Anthony 1957). No link was found, however, between social class and encopresis in general (Stein and Susser 1967, Rutter et al. 1970), or in primary encopresis specifically (Olatawura 1973).

### Diagnosis and Differential Diagnosis

Although the diagnosis can rarely be confused with other less odoriferous conditions, the main efforts during the diagnostic process are to establish the presence or absence of constipation and, to a lesser extent, distinguish continuous (primary) from discontinuous (secondary) soiling (Figure 49–2). Hersov (Taylor and Hersov 1994) listed three types of identifiable encopresis in children: (1) it is known that the child can control defeation, but she or he chooses to defecate in inappropriate places; (2) there is true failure to gain bowel control, and the child is unaware of or unable to control soiling; and (3) soiling is due to excessively fluid feces, whether from constipation and overflow, physical disease, or anxiety. In practice, there is frequently overlap among types or progression from one to another. Unlike enuresis, fecal soiling rarely occurs at night or during sleep, and if present, is indicative of a poor prognosis (Levine 1982). Soiling due to anal masturbation has been reported, although this causes staining of the sheets rather than full stools in the bedclothes (Clark et al. 1990).

### Phenomenology

In the first group, in which bowel control has been established, the stool may be soft or normal (but different from fluid-type feces seen in overflow). Soiling due to acute stress events (e.g., the birth of a sibling, a change of school, or parental separation) is usually brief once the stress has abated, given a stable home environment and sensible management. In more severe pathological family situations, including punitive management or frank physical or sexual abuse (Boon 1991), the feces may be deposited in places deliberately to cause anger or irritation, or there may be associated smearing of feces on furniture and walls. Other covert aggressive antisocial acts may be evident, with

![Figure 49–2 Diagnostic decision for encopresis.](image-url)
considerable denial by the child of the magnitude or seriousness of the problem.

In the second group, in which there is failure to learn bowel control, a nonfluid stool is deposited fairly randomly in clothes, at home, and at school. There may be conditions such as mental retardation or specific developmental delay, spina bifida, or cerebral palsy that impair the ability to recognize the need to defecate and the appropriate skills needed to defer this function until a socially appropriate time and location. In the absence of low IQ or pathological physical condition, patients have been reported as having associated enuresis, academic skills problems, and antisocial behavior. They present to pediatricians primarily and are usually younger (age 4–6 years) than other encopretic individuals. It is thought that this type of soiling is considerably more common in socially disadvantaged, disorganized multiproblem families (Anthony 1957, Berg and Jones 1964, Easson 1960) because of faulty or inconsistent training or stresses during the sensitive period of training.

In the third group, excessively fluid feces are passed, which may result from conditions that cause true diarrhea (e.g., ulcerative colitis) or, much more frequently, from constipation with overflow causing spurious diarrhea. A history of retention, either willful or in response to pain, is prominent in the early days of this form of encopresis, although later it may be less apparent because of fecal overflow. Behavior such as squatting on the heels to prevent defecation or marked anxiety about the prospect of using the toilet (although rarely amounting to true phobic avoidance) may be described.

The issue of whether a comorbid psychopathological condition is common appears to depend on where encopretic cases are sampled. Gabel et al. (1986) found some elevation in behavioral disturbance in a pediatric sample, although it was less severe than that seen in new cases in a child psychiatric outpatient clinic. Less than 13% of encopretic children had ever been referred to a mental health specialist. Similarly, Loening-Baucke et al. (1987) showed only modest elevations in Child Behavior Checklist scores and primarily in the Behavior Problem Scale. In contrast, child psychiatric studies have shown higher levels of psychopathological features, both anxiety-withdrawal and aggression (Bellman 1966, Warson et al. 1954). A large cohort study of over 8,000 children from the UK (Joinson et al., 2006) has recently examined the rates and types of psychopathology seen in children who soil frequently, occasionally, or not at all. Rates of attention-deficit hyperactivity disorder (ADHD) (9.2%, 4.0%, 1.9%) and oppositional defiant disorder (11.9%, 3.1%, 1.9%), as well as separation anxiety, social phobia, and generalized anxiety disorders (GADs), were elevated in the frequent soilers, compared to both occasional and nonsoiling controls. Controlling for developmental delay reduced the strength of the observed association but the increases remained statistically significant. A variety of antisocial behaviors (including bullying) as well as obsessive/compulsive symptoms were also seen to be associated with severity of encopresis.

Interestingly, a recent study (Stevenson and Goodman 2001) looked at the association between preschool behavior problems (measured at age 3 years) and later adult criminal convictions. It was found that the risk of having any adult conviction was related to soiling, daytime enuresis, activity level, and management difficulties, and that having an adult violent offense was related to recent-onset daytime enuresis, management difficulties, and temper tantrums. The only other predictors of later convictions were the child’s gender and social competence at age 3 years. Family and social circumstances at age 3 years did not predict later convictions.

**Issues and Further Assessment**

Having identified the presence of encopretic behavior and formed some idea of the type of encopresis (primary, secondary, or retentive, or a combination), the remaining task is to discover the presence and extent of any associated conditions, both medical and psychological. The comprehensive assessment process should include a medical evaluation, psychiatric and family interviews, and a systematic behavioral recording.

The medical evaluation comprises a history, review of systems, physical examination, and appropriate hematological and radiological tests. Although the vast majority of patients with encopresis are medically normal, a small proportion have pathological features of etiological significance. Physical causes of encopresis without retention include inflammatory bowel disease (e.g., ulcerative colitis, Crohn’s disease), central nervous system disorders, and sensory disorders of the anorectal region or pelvic floor muscles (e.g., spina bifida, cerebral palsy). Organic causes of encopresis with retention include Hirschsprung’s disease (ganglioneurosis in intermuscular and submucous plexuses of the large bowel extending proximally from the anus), neurogenic megacolon, hypothyroidism, hypercalcemia, chronic codeine or laxative usage, anorectal stenosis, and fissure (Fleisher 1976). It should also be remembered that these conditions rarely have their first presentation with encopresis alone.

The physical assessment should include an abdominal and rectal examination, although a plain abdominal radiograph is the most reliable way to determine the presence of fecal impaction. Anorectal manometry should be considered in the investigation of children with severe constipation and chronic soiling, especially those in whom Hirschsprung’s disease is suspected (Clayden and Agnarsson 1991).

Psychiatric and family interviews should include a developmental history and a behavioral history of encopresis (antecedents, behavior, and consequences). Specific areas of stress, acute or chronic, affecting the child or family, or both, should be discovered. Associated psychopathological conditions are more commonly found in the older child, in secondary encopresis, and when soiling occurs not only in clothes. Anxiety surrounding toileting may indicate phobia, coercive toileting, or a history of painful defecation. A history should be obtained of the parents’ previous attempts at treatment together with previously prescribed therapy so that reasons for previous failure can be identified and anticipated in future treatment planning.

**Treatment**

Practical management for encopresis is presented in Table 49–3.

**Standard Treatment**

The principal approach to treatment is predicated on the results of the evaluation and the clinical category assigned.
This differentiates between the need to establish a regular toileting procedure in patients in whom there has been a failure to learn this social behavior and the need to address a psychiatric disorder, parent–child relationship difficulties, or other stresses in the child who exhibits loss of this previously acquired skill in association with these factors. In both cases, analysis of the soiling behavior may identify reinforcing factors important in maintaining dysfunction. Detection of significant constipation will, in addition, provide an indication for adjuvant laxative therapy.

Behavioral Treatments
Behavioral therapy is the mainstay of treatment for encopresis. In the younger child who has been toilet trained, this focuses on practical elimination skills, for example, visiting the toilet after each meal, staying there for a maximum of 15 min, using muscles to increase intra-abdominal pressure, and cleaning oneself adequately afterward. Parents or caretakers, or both, need to be educated in making the toilet a pleasant place to visit and should stay with the younger child, giving encouragement and praise for appropriate effort. Small children whose legs may dangle above the floor should be provided with a step against which to brace when straining. Initially, a warm bath before using the toilet may relax the anxious child and make it easier to pass stool. Systematic recording of positive toileting behavior, not necessarily being clean (depending on the level of baseline behavior), should be performed with a personal star chart. For the child with severe anxiety about sitting on the toilet, a graded exposure scheme may be indicated.

Role of the Family in Treatment
Removing the child’s and family’s attention from the encopresis alone and focusing onto noticing, recording, and rewarding positive behavior often defuses tension and hostility and provides the opportunity for therapeutic improvement. Identifying and eliminating sources of secondary gain, whereby soiling is reinforced by parental (or other individuals’) actions and attention, even if negative or punitive, make positive efforts more fruitful. Some investigators advocate mild punishment techniques, such as requiring the child to clean his or her own clothes after soiling (Doleys et al. 1977), although care must be taken to prevent this from becoming too punitive. In certain settings, particularly school, attempts are made to prevent soiling by extremely frequent toileting that, although keeping the child clean, does not promote and may even hinder the acquisition of a regular bowel habit. Formal therapy, either individual or family based, is indicated in only a minority of patients with an associated psychiatric disorder, marked behavioral disturbance (e.g., smearing, other aggressive soiling), or clear remediable family or social stresses.

Physical Treatments
In patients with retention leading to constipation and overflow, medical management is nearly always required, although it is usually with oral laxatives or microenemas alone. The use of more intrusive and invasive colonic and rectal washout or surgical disimpaction procedures is nearly always the result of the clinician’s impatience rather than true clinical need.

Uncontrolled studies of combined treatment with behavioral therapy and laxatives reported marked improvement in symptoms (not cure) in approximately 70–80% of patients (Levine and Bakow 1976, Loening-Baucke 1992). Berg et al. (1982) reported the first double-blind randomly controlled trial of the laxative Senokot (senna concentrate) and behavioral therapy, which showed no significant advantage for the laxative by 3 months. A more recent controlled randomized trial (Nolan et al. 1991) comparing behavioral therapy in retentive primary encopresis with and without laxatives showed that at 12-month follow-up, 51% of the combined treatment (laxative plus behavioral therapy) group had achieved remission (at least one 4-week period with no soiling episodes), compared with 36% of the behavioral therapy only group (p = 0.08). Partial remission (soiling no more than once a week) was achieved in 63% of patients with combined therapy versus 43% with behavioral therapy alone (p = 0.02). Patients receiving laxatives achieved remission significantly sooner, and the difference in the Kaplan–Meier
remission curves was most striking in the first 30 weeks of follow-up (p = 0.012). When patients who were not compliant with the toileting program were removed from the analysis, however, the advantage of combined therapy was not significant. These results must also be viewed in light of Bellman’s (1966) findings in a follow-up study of 186 clinic patients with encopresis, which reported a 50% spontaneous remission rate at 2 years. It should also be noted that approximately 15–20% of patients fail to respond to or comply adequately with initial combined treatment (Levine 1982, Nolan et al. 1991).

Biofeedback Therapy
The finding that some children with treatment-resistant retentive encopresis involuntarily contract the muscles of the pelvic floor and the external anal sphincter, effectively impeding passage of stool (Loening-Baucke and Cruickshank 1986), has led to efforts to use biofeedback in this instance. Olness et al. (1980) used visual feedback of internal and external sphincter pressures measured by an anal balloon in 40 children, who were chronic soilers, in whom conventional treatment had failed in association with emphasizing regular toileting. Normal bowel habits were acquired by 24 children (Doyley et al. 1977). It has similarly been reported that as few as six sessions of biofeedback therapy can lead to a significant reduction in symptom frequency for as many as 86% of previously treatment-resistant patients (Loening-Baucke 1995). This has been challenged by van Ginkel et al. (2001) who showed that anorectal manometry offered no additional advantage over conventional therapy (dietary advice, diary, toilet training, oral laxatives, and enemas) in chronic constipation/encopresis. It is possible, however, that biofeedback is principally of benefit to nonretentive chronic soilers (van Ginkel et al. 2000).

Clinical Vignette 2
John was a 6-year-old boy, the only child of a farmer and his wife both of whom had strong obsessional traits and were excessively fastidious and house-proud. As a 6-month-old baby, John had been prescribed senna for about 3 months around the time he began a fully solid diet. He was investigated for Hirschsprung’s disease, but rectal biopsy results were negative. Toilet training was started at age 15 months because his mother was anxious to have John out of diapers by the age of 2 years. Accordingly, John was placed on the “pot” whenever he appeared to need it. This averaged 15 times a day. He would eat sitting on the pot and watch television there, and the family would not travel anywhere without this receptacle just in case John showed any sign of needing to evacuate his bowels. When, by age 2 years, John had not established a regular toileting habit, the parents gave up and placed him back in diapers. A further brief yet frenzied effort at training occurred at age 3 years because he would be unable to attend a local pre-school program if he was not bowel trained. Not surprisingly, John was not permitted to attend nursery school. Soon after starting kindergarten, his school became exasperated with John who was soiling his clothes with almost fluid feces on a regular basis. After consulting with his mother, they assigned John a nonteaching aide who, in a fashion similar to John’s mother, be responsible for taking him to the bathroom on an increasingly frequent basis. When John continued to soil his pants despite hourly toileting, the school urged John’s parents to seek a specialist referral.

On presentation, John seemed to be a bright, if somewhat indolent, child who on the surface was not bothered by his soiling, but on further examination was upset by the fact that he had few friends and was not allowed to go swimming with his class. Physical examination showed a distended abdomen, with marked fecal impaction around the hepatic flexure of the colon. He was prescribed lactulose and senna twice daily, and a toileting program was designed. Because he was a fan of the television characters the Power Rangers, an elaborate chart embodying the important elements of this show was designed in consultation with John. Initial targets consisted of going to the bathroom for 15 min after each meal, with initial stars given for trying to pass anything. His mother was taught to place a hand on his abdomen to check for adequate muscular effort. Later behavioral targets became progressively more difficult. Soiling was deemphasized, and considerable effort was expended in assuaging parental anxiety that John would ever be able to pass the accumulated fecal masses. After 5 days, an enormous amount of feces was passed in the evening after a warm bath. Both John and his mother were overjoyed. This pattern was repeated over the next week, with an abdominal radiograph confirming that the colon and rectum were no longer impacted. By 6 weeks, John had established a regular thrice-daily toileting pattern, with only once-weekly accidents. Despite a high-fiber diet, efforts to reduce the laxatives completely were thwarted by recurrent retention, and the decision was made to continue with long-term fecal softeners. By 6 months, John was completely clean.

Other Disorders Specific to Children and Adolescents
Compared to the Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (Oppel et al. 1968), DSM-IV (Rutter et al. 1973) eliminated over-anxious and avoidant disorders with the thought that the criteria sets for GAD and social phobia (SP) could be successfully applied to the majority of anxious children with those diagnoses. With these changes, the only unique anxiety disorder of children and adolescents remaining is separation anxiety disorder (SAD). It remains unclear how successful this nosological change will prove to be, since, although the GAD criteria set has shown some validity in distinguishing GAD children from those with other anxiety disorders (Tracey et al. 1997), it is likely that a large number of subjects previously diagnosed with overanxious disorder do not meet GAD criteria.

Selective mutism (SM), the failure to speak in certain social situations, although not currently classified as an anxiety disorder, has shown a strong association with social phobia and appears to respond, sometimes dramatically, to anxiolytic medication (Dummit et al. 1997).

SAD
Definition
SAD is typified by developmentally inappropriate and excessive anxiety concerning separation from home or attachment figures (see DSM-IV-TR for SAD).
Separation Anxiety Disorder

A. Developmentally inappropriate and excessive anxiety concerning separation from home or from those to whom the individual is attached, as evidenced by three (or more) of the following:

1. recurrent excessive distress when separation from home or major attachment figures occurs or is anticipated
2. persistent and excessive worry about losing, or about possible harm befalling major attachment figures
3. persistent and excessive worry that an untoward event will lead to separation from a major attachment figure (e.g., getting lost or being kidnapped)
4. persistent reluctance or refusal to go to school or elsewhere because of fear of separation
5. persistently and excessively fearful or reluctant to be alone, or without major attachment figures at home, or without significant adults in other settings
6. persistent reluctance or refusal to go to sleep without being near a major attachment figure or to sleep away from home
7. repeated nightmares involving the theme of separation
8. repeated complaints of physical symptoms (such as headaches, stomachaches, nausea, or vomiting) when separation from major attachment figures occurs or is anticipated

B. The duration of the disturbance is at least 4 weeks.

C. The onset is before age 18 years.

D. The disturbance causes clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.

E. The disturbance does not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and, in adolescents and adults, is not better accounted for by panic disorder with agoraphobia.

Specify if:

Early Onset: if onset occurs before age 6 years.

Natural History and Course

The community prevalence of SAD is generally estimated to be around 4% in children and young adolescents; it decreases in prevalence from childhood through adolescence (Moreau and Weissman 1993). A recent large twin study reported that at age 6, the prevalence was 7.4% for DSM-IV-defined SAD (using symptom criteria only) but only 2.8% when requiring clinically significant impairment (Bolton et al. 2006). As with community subjects, in clinically referred children and adolescents (aged 5–18 years) with anxiety disorders, SAD is found (Last et al. 1992) to be the most frequently occurring disorder, with a lifetime prevalence of 44.7%. The age of onset has been reported to be 4–7 years, with earlier onset being associated with clinical status and comorbidity (Biederman et al. 1997, Keller et al. 1992). However, in a recent study (Egger and Angold 2006) of preschool children (aged 2–5 years), SAD was found in 2.4%. Separation anxiety, particularly in younger samples, is found more frequently in girls than boys—with a ratio as high as 2.5:1 (Anderson et al. 1987). In a 3–4-year prospective study (Last et al. 1996) of subjects with anxiety disorders, 29% of children had SAD (21% had SAD as their primary diagnosis) at baseline. On follow-up, 92% of children previously diagnosed with SAD no longer had symptoms that met full criteria for SAD, although 25% had developed a new disorder, most frequently a depressive disorder. Finding that 50% of adult panic patients had experienced separation anxiety during childhood, it has been hypothesized (Gittleman and Klein 1984) that separation anxiety may be a childhood precursor to adult panic disorder and agoraphobia. In a study (Zitrin and Ross 1988) using a phobic control group, 48% of female agoraphobia patients had previous separation anxiety, as opposed to 20% of controls. Rates among males were not significantly different, however. The influence of comorbidity is also important in understanding the link between parental and offspring anxiety disorders. Although rates of separation anxiety are increased in the offspring of mothers with panic disorder, this has been found to be largely the result of parental separation anxiety (Biederman et al. 2006). A specific link between maternal phobic anxiety and child separation anxiety has also been demonstrated (Bernstein et al. 2005). In all, the evidence is uneven and it is difficult to be definitive since most studies are retrospective, focus on separation anxiety symptoms rather than the full disorder, and/or fail to include an appropriate control group.

Etiology and Pathophysiology

Sensitivity to suffocation cues, important in the carbon dioxide (CO₂) challenge paradigm in panic disorder and respiratory response, may differentiate children with anxiety disorder, and separation anxiety in particular, from children without an anxiety disorder (Pine et al. 1998). Inhalation of air containing raised CO₂ concentration results in increased catecholamine release throughout the body and perceived anxiety. This response appears mediated via the locus coeruleus, a group of norepinephrine-containing neurons originating in the pons and projecting to all major brain areas. The locus coeruleus forms part of the reticular activating system (RAS) and functions to regulate noradrenergic tone and activity. Hypothalamic and thalamic nuclei also play a role in the perception of and response to external threats. They act by transmitting arousal information from the RAS to limbic and cortical areas involved in sensory integration and perception. The thalamus is thought to have a role in the perception of anxiety, whereas the hypothalamic nuclei mediate the response by the neuroendocrine system.
Experiments in rhesus monkeys inducing separation anxiety suggest roles for both the locoregional/noradrenergic system as well as the hypothalamic-pituitary axis (HPA) (Chrousos and Gold 1992). Urinary cortisol has been shown to be raised (indicative of HPA overactivity) in infants aged 1 year who demonstrated extreme distress when separated from their primary attachment figure (Tenes et al. 1977).

Separation anxiety, when developmentally appropriate, is seen via attachment theory as an adaptive response that infants use to enhance proximity to their caregivers (Bowlby 1973). In this, when the infant has adequate proximity to the caregiver in a given context, attachment behaviors (separation anxiety symptoms) subside and are replaced by alternate behaviors. On the basis of their response to various experimental paradigms, infants can be categorized into having a different type of attachment. Although the nosology of attachment has varied, the most frequently described type of pathological attachment is known as “insecure attachment.” Excessive distress on separation evinced by insecurely attached infants appears to be the earliest manifestation of SAD, but this pattern is not specific, in that it can be the precursor of other types of anxiety (e.g., social phobia/avoidant disorder, panic disorder) in childhood (Manassis et al. 1995) and adolescence.

Parenting behaviors are also hypothesized as being involved in the etiology of separation anxiety. Anxious parenting, possibly in response to observed distress in the child, seeks to prevent the child from experiencing further distress, thereby limiting exposure and the development of adaptive coping. Parental intrusiveness, a tendency to take over tasks that children are (or could be) performing independently, leads to failure by the child to experience mastery, and to develop inappropriate dependence on the parent. Such intrusiveness has been found (Wood 2006) to be linked to child separation anxiety, but not to other anxiety disorders.

### Diagnosis and Differential Diagnosis

The assessment strategy will depend upon the child’s age, symptom profile, the sources of available information, and the purpose of the assessment. As discussed above, separation anxiety is normal at some ages and is maximal around 14 months of age (Crowell and Waters 1990). A study by Last et al. (1992) of outpatients with SAD revealed age differences but no gender differences in symptom profile and numbers of symptoms. The most prevalent symptoms in young children (aged 5–8 years) are worry about losing or about possible harm to an attachment figure, and reluctance or refusal to go to school. Children aged 9–12 years most frequently reported recurrent excessive distress when separated from home or attachment figures, whereas adolescents (aged 13–16 years) had physical symptoms on school days. More symptoms were reported with decreasing age.

The usual unstructured clinical interview can, in view of its poor reliability and variable symptom coverage, be supplemented by standardized diagnostic interviews such as the Diagnostic Interview Schedule for Children (DISC) or the Anxiety Disorder Interview Schedule (ADIS) which have shown acceptable test–retest reliability and validity (Shaffer et al. 1999, Silverman and Rabian 1995). In addition, there are a large number of self-report questionnaires that can assess children’s fears and anxieties, either to detect anxiety disorders in community samples or to distinguish between the different anxiety disorders in clinically referred children. The most useful of these are the Multidimensional Anxiety Scale for Children (MASC) (March et al. 1997) and the Screen for Child Anxiety Related Emotional Disorders (SCARED) (Birmaher et al. 1997). These have been shown to have good test–retest reliability, internal consistency, and can differentiate not only anxious children from nonanxious children but also distinguish specific anxiety disorders from each other. Particularly with younger children, there is value to direct observation of the child either in determining the diagnosis or in behavioral analysis (Glennon and Weisz 1978).

Other issues in assessment of separation anxiety include: the relative value of information from differing methodologies (i.e., unstructured interview, structured interview, self-report questionnaires, and direct observation), how to integrate information from separate informants, and also the cultural validity of most measures of anxiety.

Differential diagnoses to consider include GAD, where the anxiety is more free-floating, less situation-specific and occurs independent of separation from the primary attachment figure, and social phobia. Children with social phobia will display a fear of social situations where they may be the object of public scrutiny. This anxiety may be ameliorated by the presence of a familiar person but will not occur exclusively when the attachment figure is absent, as with separation anxiety.

School refusal has long been associated with SAD, though this relationship holds mainly for younger children when school nonattendance is most closely linked to fear of separation, whereas in adolescents fear of school and other social situations in which they feel they are being evaluated is more typical. It is important in the assessment of school nonattendance, a frequent impairment associated with SAD, to distinguish anxiety-related school refusal from conduct disorder–related truancy. Typically the school-refusing child will stay at home or with parents, whereas the truanting child will go off with peers. In the presence of school refusal, a useful approach (Kearney and Silverman 1999) is to attempt to categorize the behavior as fulfilling one of the following functions:

1. Avoidance of stimuli provoking specific fearfulness or anxiety (e.g., separation).
2. Escape from aversive social or evaluative situations (e.g., social phobia).
3. Attention-getting behavior (e.g., physical complaints/tantrums).
4. Positive tangible reinforcement (e.g., parental collusion).

### Treatment

Following a good behavioral and functional analysis, the most frequently employed clinical approach to the treatment of separation anxiety and school refusal is behavioral. The principles of systematic desensitization to feared objects or situations will be employed, gradually increasing the amount of separation that can be tolerated in a graduated fashion. Systematic desensitization usually has three components. Firstly, a response incompatible with anxiety (often progressive muscular relaxation, but can be imagery or breathing exercises) is taught. The second component
Pharmacological treatment studies of separation anxiety have tended to focus on samples with school refusal behavior and various diagnostic status or on subjects with a variety of comorbid anxiety disorders including SAD. Early studies (Klein et al. 1992, Berney et al. 1981) used imipramine or clomipramine with varying success (the presence of separation anxiety was not specifically associated with treatment response). More recently, the Research Unit on Pediatric Psychopharmacology Anxiety Study Group (2002) investigated 128 children with anxiety disorders (social phobia, SAD, and/or GAD aged 6–17 years). Subjects who failed to respond to an initial 3 weeks of psychological treatment were randomly assigned to a double-blind, placebo-controlled trial of fluvoxamine up to a maximum of 300 mg/day for 8 weeks. Children randomized to fluvoxamine showed significantly greater drops in anxiety disorder symptoms compared to placebo ($p < 0.001$). Pure cases of separation anxiety were very hard to find in this clinical sample, but therapeutic effect was seen in all symptom areas. A study (Birmaher et al. 2003) of 74 children and adolescents aged 7–17, again with mixed anxiety disorders (SAD, Social Phobia and GAD), showed 61% of subjects on fluoxetine to have significant improvement in global functioning compared to only 35% of controls.

Considering safety and efficacy, the SSRIs appear to be the first-line treatment for SAD, but more studies are needed to confirm preliminary results. SSRIs treatment in responders should be continued for a 1-year period, but there are little data to support this. Tricyclic antidepressants and benzodiazepines may be considered when the child has not responded to SSRIs or when adverse effects have exceeded benefits. There is very little evidence on the treatment of children younger than 6 years of age—and specifically there are no controlled trials that attempt to evaluate a treatment specifically for young anxious children. This lack of evaluated treatment options is concerning in light of mounting evidence that many anxiety disorders have a very early onset, and that separation anxiety is not uncommon in this age group.

In practice, however, clinicians often combine drug and psychosocial treatments, capitalizing on differences in dose-response and time-response parameters. There is some evidence that treatments can be additive (each treatment having unique benefits) or synergistic (the benefit of the combination is greater that the additive combination). Alternatively, when combining drug and psychosocial treatments, a lower dose of one or both may be possible, with a resultant decrease in expense, inconvenience, or adverse events. Drug effects are often seen sooner than those due to exposure-based therapy, though it is hoped that the slower to emerge benefits of therapy may be more long lasting.

Clinical Vignette 3

Alex was an 8-year-old boy who lived with both parents and was referred by his pediatrician with a history of school refusal and recurrent abdominal pain, for which no organic cause could be found. Since commencing middle school (which begins at grade 3) Alex had been reluctant to separate from his mother, with frequent physical
complaints on school mornings. He expressed little anxiety verbally, though he was clingy and acted younger than his stated years. At the time of presentation, Alex had been off school for 5 weeks. Despite negative physical and radiological examinations, Alex continued to complain of severe stomach pains and nausea that prevented him from attending school.

Alex’s symptoms first occurred at age 4 when he was unable to tolerate separation at pre-kindergarten. If left there he would frequently become so distressed that he would end a crying spell with vomiting, at which point his mother would be summoned and Alex would return home with her. Starting Kindergarten there were similar separation anxiety problems. These persisted for 3 months, though his school attendance was ensured by being dropped off by father on his way to work. In 1st and 2nd grades, anxiety symptoms were transitory at the start of each new school year and following return from extended vacation periods, but were not associated with significant school absence.

The current symptoms occurred during the summer vacation, prior to changing schools for 3rd grade. They were precipitated by Alex suffering a bout of food-poisoning. Mother, who had Crohn’s disease, nursed him most assiduously and when Alex started having recurrent abdominal pain, worried that he had the juvenile form of this disorder. He developed increasing separation anxiety, following the mother from room to room. He became concerned about a rash of recent burglaries and that his mother would be home alone in the mornings once he returned to school. Alex was reluctant to sleep alone in his own room and began to require his mother to lie alongside him until he dropped asleep.

Upon interview Alex was a small pale child who clung excessively to his mother and frequently looked at her prior to answering questions. Father, appearing somewhat impatient sat at some distance from his wife and Alex. It was apparent early on that the relationship between parents was strained with obvious dissonance between mother and father about the nature, cause, and required management of Alex’s symptoms. After a lengthy session, mother seemed a little more willing to accept that Alex’s abdominal symptoms were anxiety related and that continued absence from school was counterproductive. It was agreed that, after discussion with his school, Alex would return promptly to school on the following Monday and that the family would return for a further session after school on Wednesday.

On their return it was reported that Alex had become unwell on Sunday night, and, although the family were fairly clear that he wasn’t severely ill, mother took him to the pediatrician in the morning and on to school for the afternoon session. Although he remained at school, after marked initial distress, he came home very angry with his mother, and she was reluctant to take him the following day. Alex was willing to speak on his own to the psychiatrist, and he disclosed numerous fears about the welfare of his mother and his belief that she needed him for the care of Alex’s symptoms. After a lengthy session, mother was willing to accept that Alex’s abdominal pain, and for remaining at school. This approach proved successful and Alex was able to attend school. Abdominal pain was much reduced and over the next few weeks Alex was able to verbalize more of his fears and concerns about whether his parents would get divorced (it was later disclosed that the parents had a brief separation during the early part of the year). Ongoing cognitive–behavioral sessions focused on Alex’s fears and on strategies to encourage greater independence (couched in terms of “growing up”). Following the winter break, Alex once more expressed reluctance to return to school, but with encouragement (and firm expectations by both parents) he did not miss attendance, despite a great deal of anticipatory anxiety.

**Selective Mutism**

**Definition**

The essential feature of selective mutism is the persistent failure to speak in specific social situations (e.g., school, or with peers) where speaking is expected, despite speaking in other situations (e.g., home) (see DSM-IV-TR for Selective Mutism).

**Epidemiology**

Previously referred to as elective mutism, in DSM-IV-TR the condition was renamed selective mutism, so as to be less judgmental (doesn’t speak rather than chooses not to speak). The prevalence is usually reported as 0.6–7 per 1,000 (Brown and Lloyd 1975, Fundudis et al. 1979), with higher incidence in females rather than males (Hayden 1980).

When subjects failing to speak in the first few weeks of school (a DSM-IV-TR requirement) are excluded, rates

---

**Selective Mutism**

**A.** Consistent failure to speak in specific social situations (in which there is an expectation for speaking, e.g., at school) despite speaking in other situations.

**B.** The disturbance interferes with educational or occupational achievement or with social communication.

**C.** The duration of the disturbance is at least 1 month (not limited to the first month of school).

**D.** The failure to speak is not due to a lack of knowledge of, or comfort with, the spoken language required in the social situation.

**E.** The disturbance is not better accounted for by a communication disorder (e.g., stuttering) and does not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder.

do not exceed 2 per 1,000. Onset is usually in the pre-school years, but the peak age of presentation and diagnosis is between 6 and 8 years (Dow et al. 1995). A study of the long-term outcome of selective mutism has recently been reported (Steinhausen et al. 2006). This showed that the symptoms had improved considerably by young adulthood. However, the selectively mute children did have significantly higher rates of phobic disorder (42% vs. 0%) and any psychiatric disorder (57% vs. 23%) than controls at follow-up (mean age 21.5 years).

A high incidence of insidious onset of refusal to speak with anyone except family members is reported. The other typical picture is one of acute onset of mutism on starting school (Hayden 1980, Kolvin and Fundudis 1981).

Etiology

Three basic theories have been proposed to explain the etiology of selective mutism and describe distinct groups of children: children who are negative, oppositional, and controlling; traumatized children; and children who have severe anxiety, chiefly social phobia. Although early psychodynamic theorists (Hayden 1980) described an enmeshed relationship between mother and child, the father being distant and ineffectual, and a conflicted relationship between the parents, controlled studies of selective mutism do not find family functioning worse compared to the families of other emotionally disturbed children (Kolvin and Fundudis 1981, Wilkins 1985) or children with social phobia (Yeganeh et al. 2006). Associated features include a history of delayed speech and articulation problems, and possibly, increased incidence of enuresis and/or encopresis (Dow et al. 1995, Kolvin and Fundudis 1981, Wilkins 1985). There may be a family history of general shyness, or of elevated levels of anxiety in the parents (Hayden 1980, Kolvin and Fundudis 1981). A recent review (Cohan et al. 2006) suggests that selective mutism develops due to a series of complex interactions (e.g., a strong genetic loading for anxiety interacts with an existing communication disorder, resulting in heightened sensitivity to verbal interactions and mutism in some settings). In children with selective mutism as well as meeting DSM-IV criteria for Social Phobia, more than half also meet criteria for another comorbid disorder, including generalized anxiety (26%) and oppositional defiant (29%) disorder (Yeganeh et al 2006). These rates are higher than those seen in social phobia not complicated by failure to speak in certain situations.

Assessment

Prior to making a diagnosis of selective mutism, a comprehensive evaluation should be conducted to rule out other explanations for mutism and to assess important comorbid factors. For obvious reasons, the parental interview will form the mainstay of evaluation but, as discussed below, direct observation (and interview if possible) of the child can afford important diagnostic information.

It is important to obtain information of the nature of the onset (insidious or sudden), any uncharacteristic features (i.e., not talking to family members, abrupt cessation of speech in one setting, absence of communication in all settings) suggestive of other neurological or psychiatric disorders (e.g., pervasive developmental disorders, acquired aphasias), and any history of neurological insult/injury, developmental delays, or atypical language and/or speech. The assessment should also include the degree to which nonverbal communication or non-face-to-face communication is possible, the presence of anxiety symptoms in areas other than speaking, social and behavioral inhibition, and medical history including ear infections, and hearing deficiencies. Parents will be able to give information on where and to whom the child will speak, the child’s speech and language complexity at home, articulation problems, use of nonverbal communication (e.g., gestures), any history of speech and language delays, and the possible importance of bilingualism (where primary language is not English). It can be useful to have the parents provide an audiotape of the child speaking at home.

The child evaluation can assess the presence of anxiety and social inhibition (willfulness to communication through gesture or drawing). Physical examination of oral sensory and motor ability may provide evidence of neurological problems (i.e., drooling, asymmetry, orofacial weakness, abnormal gag reflex, impaired sucking or swallowing). Specialist audiometry (pure tone and speech stimuli as well as tympanometry and acoustic reflex testing) may provide evidence of hearing and/or middle ear problems that can have a significant effect on speech and language development. Cognitive abilities may be difficult to assess, but the performance section of the WISC-R (Wechsler 1974) or Raven’s Progressive Matrices (Raven 1976) as well as the Peabody Picture Vocabulary Test (Dunn and Dunn 1981) may be useful in the nonverbal child.

Treatment

Treatment has long been regarded as difficult and prognosis poor. Approaches have included behavioral therapy, family therapy, speech therapy, and more recently, pharmacological agents (Cline and Baldwin 1994). Unfortunately most published studies are single case reports, with very few controlled studies.

Behavioral treatment focuses on mutism as a means of getting attention and/or escaping from anxiety. A controlled study (Calhoun and Koenig 1973) of eight subjects with random assignment to treatment (teacher and peer reinforcement of verbal behavior) or control showed significant increases in mean number of vocalizations after 5 weeks of treatment. These gains were not, however, maintained at 12-month follow-up. Other techniques have included graded exposure, shaping, and modeling. The goal of a treatment program should be to decrease the anxiety associated with speaking whilst encouraging the child to interact verbally.

Regarding pharmacotherapy, early success with phenelzine in a 7-year-old girl with mutism and shyness (Golwyn and Weinstock 1990) led to the use of SSRI medication in cases of selective mutism with associated anxiety (principally social phobia). Successful case reports were followed by open and controlled studies using fluoxetine. An open trial of 21 children using a mean dose of 28.1 mg/day showed improvement in 76% of cases (Dummit et al. 1996). A placebo-controlled double-blind study showed mixed results, though both groups remained highly symptomatic. More chronic (>14 weeks) treatment was recommended (Black and Uhde 1994).
Comparison of DSM-IV/ICD-10 Diagnostic Criteria

In contrast to DSM-IV-TR, which establishes a minimum duration of 3 months for encopresis, the ICD-10 Diagnostic Criteria for Research has set a minimum duration of 6 months. In ICD-10, this disorder is referred to as “Nonorganic Encopresis.”

For enuresis, the ICD-10 Diagnostic Criteria for Research have a different frequency threshold: at least twice a month in children aged under 7 years and at least once a month in children aged 7 years or more. In contrast, DSM-IV-TR requires either a frequency of twice a week for at least 3 consecutive months (regardless of age) or else the presence of clinically significant distress or impairment. Furthermore, ICD-10 includes a very strict exclusion criterion, preventing a diagnosis of enuresis to be made if there is any evidence of another mental disorder. In ICD-10, this disorder is referred to as “nonorganic enuresis.”

For SAD, the DSM-IV-TR and ICD-10 symptom items are almost identical. The ICD-10 Diagnostic Criteria for Research are narrower in that the age of onset must be before age 6 and the diagnosis cannot be made if the presentation is “part of a broader disturbance of emotions, conduct, or personality.” The DSM-IV-TR criteria and ICD-10 Diagnostic Criteria for Research for selective mutism are almost identical. In ICD-10, the disorder is referred to as “elective mutism.”

References

This chapter describes two disorders that tend to occur in association with socially deprived environments, most often occurring in individuals who have developmental delays or mental retardation. Stereotyped Movement Disorder involves abnormal motor behaviors and Reactive Attachment Disorder (RAD) involves abnormal social behaviors.

**Stereotyped Movement Disorder**

Stereotypic Movement Disorder is characterized by repetitive, seemingly driven, nonfunctional movements including hand waving, head banging, body-rocking, fiddling with fingers, self-biting, or hitting various parts of one's own body. These behaviors can be problematic for a number of reasons because they may result in self-injury, affect general health, result in significant social stigmatization, interfere with acquisition of new skills, and interfere with performance of existing skills.

**Definition and Diagnostic Features**

Stereotyes are repetitive, driven, and nonfunctional motor behavior. Stereotypic Movement Disorder is defined in the DSM IV-TR (American Psychiatric Association 1999) as stereotypic movements that interfere with regular functioning or cause self-injury that requires medical intervention or would if the stereotypic movement was not restricted. Several similar conditions are excluded, including stereotypic movements in the setting of pervasive developmental disorder, trichotillomania, compulsions, and substance use. While these are exclusions from the diagnosis of Stereotypic Movement Disorder, some of these exclusions will be touched on in this section, as they contribute some information about pathophysiology of stereotypic movements and self-injurious behaviors.

Berkson (1983) described stereotypies as voluntary, lacking variability, persisting over time, being immutable even when the environment changes and being inconsistent with the person's expected development.

The self-injurious behavior discussed in this chapter occurs in conjunction with stereotypic movements, which may or may not be different from other self-injurious behaviors, particularly those associated with affective, psychotic, and personality disorders. Those self-injurious behaviors tend to be more episodic and associated with cognitions, depersonalization, and negative feelings about oneself. The self-injurious behaviors associated with stereotypic behaviors have a more repetitive and driven quality to them.

**Assessment**

Stereotypic movements are problematic when they interfere with a person's overall functioning, become socially stigmatizing, or result in self-injury. They can be observed by
clinicians, reported by caregivers, or reported by the patient. Since a visit to a clinic or from a provider may be a stimulating experience, the stereotypic movement may not be readily observable by a clinician. Stereotypic movement ratings are part of several assessment scales designed for individuals with intellectual disabilities and Pervasive Developmental Disorders. For example, the Diagnostic Assessment for the Severely Handicapped-II (DASH-II) (Sturmey et al. 2004), has a scale for stereotypic movements and another for self-injurious behavior. The Stereotyped Behavior Scale (SBS) (Rojahn et al. 1997) was developed as a behavior rating scale for adolescents and adults with mental retardation. The common feature of scales used to assess stereotyped behavior is that they ask a clinician, caregiver, or patient to report on direct observations of behavior.

**Epidemiology**

Stereotypic movements are relatively common. For example, as many as 90% of typically developing children engage in body rocking as a normal part of motor development, and 10% of normally developing 2-year-olds engage in head-banging while having tantrums (Berkson et al. 2001). Stereotypic movements are present but rare in populations of adults with average intelligence (Mendez and Mirea 1998) These behaviors are predictably longer-lived and more impairing in developmentally delayed populations. In fact, the more severe the level of retardation, the more likely the person is to exhibit stereotypic movements, and the more likely these stereotypic movements will be self-injurious.

Another study found that individuals with profound mental retardation were more likely to have stereotypic behaviors and self-injury than those with severe mental retardation (Matson et al. 1997) New York and California state agency data sets of more than 130,000 people with mental retardation also showed increasing amounts of self-injurious behavior with increasing deficits in functioning (Schroeder et al. 2001).

More severe forms of stereotyped behavior with self-injury occurred in 4.6% of a sample of 3- to 40-month-old children with developmental disabilities. Less severe forms of stereotyped behavior were much more common, however; 100% of the children in this sample engaged in body rocking (Berkson et al. 2001). Other studies have shown as many as 17% of individuals with developmental disabilities engaging in repetitive self-injurious behavior, some very frequently (Schroeder et al. 2001). Although up to two-thirds of adults with mental retardation living in institutions exhibited stereotypic behavior, the number of adults with mental retardation also showed increasing amounts of self-injurious behavior with increasing deficits in functioning (Schroeder et al. 2001).

**Comorbidity**

Stereotypic Movement Disorder occurs most frequently in people with mental retardation, or pervasive developmental disorders. Because they both are related to conditions of neglect, Stereotypic Movement Disorder may co-occur with RAD. Several other conditions are also associated with stereotypic movements. Some genetic syndromes associated with Stereotypic Movement Disorder are Lesh-Nyhan Syndrome, associated with stereotypic self-hitting of the forearms, Prader-Willi Syndrome associated with skin picking of the back of the hands, and Fragile X Syndrome.

**Differential Diagnosis**

The stereotypic behaviors of Stereotypic Movement Disorder must be distinguished from a variety of other movements. Like most other DSM-IV TR diagnoses, the behaviors must be severe enough to cause impairment in functioning. Stereotypic Movement Disorder is often diagnosed in people with Mental Retardation. However, stereotypic movements are considered a feature of Pervasive Developmental Disorders and therefore would not be given a separate diagnosis when they occur in such individuals. Tics are generally simpler motor movements with a less-driven quality, however, some complex tics can be more difficult to differentiate from stereotypic movements. Neurological conditions with involuntary movements also tend to follow recognizable patterns that are typical for the neurological condition, and generally have a less driven quality. Tardive dyskinesia also follows generally recognizable patterns, including following antipsychotic use and having typical facial or truncal movements.

Stereotypic Movement Disorder must also be distinguished from a variety of different behaviors. Compulsions associated with Obsessive-Compulsive Disorder can look like stereotypic movements. Compulsions, though, are generally more complex than stereotypic behaviors. Compulsions are performed in order to reduce anxiety associated with an obsessive thought and compulsions are usually associated with rigid rules (e.g., washing left hand first twenty times, followed by the right hand twenty times).

Developmentally appropriate self-stimulatory behaviors such as thumb sucking can be differentiated from Stereotypic Movement Disorder by the appropriateness of the behavior to the patient’s developmental level, changes in the behavior in response to the environment, and extinction of the behavior as the patient progresses in development.

Trichotillomania is another condition that must be distinguished from stereotypic movement disorder. By definition, trichotillomania refers only to hair pulling, and while it may be similar in repetitiveness, have a similar driven quality, and result in similar self-harm, it should not also be diagnosed as Stereotypic Movement Disorder. Factitious Disorder with Predominantly Physical Signs and Symptoms can be differentiated from Stereotypic Movement Disorder because the purpose of the movements is for medical attention.

Self-mutilation associated with Personality Disorders, Mood Disorders, and Psychotic Disorders can also be differentiated from Stereotypic Movement Disorder. The self-mutilation of Stereotypic Movement Disorder is associated with the repetitive, driven movement. Self-mutilation in other disorders is not associated with a movement, but rather with depersonalization, cognitions, and feelings about one’s self.

**Etiology and Pathophysiology**

Stereotypic Movement Disorder has a multifactorial pathophysiology involving a complex interaction between several neurological pathways, psychological factors, and social factors.
Neurobiological Factors
Considerable research had addressed the neurobiology of stereotypies. Dopaminergic, serotonergic, and endogenous opioid systems have been associated with stereotypic movements and self-injurious behavior.

The dopaminergic system, specifically hypodopaminergic function in the striatum, has been tied to the development of stereotypic movements. Animal studies show a link between early deprivation, disruption of the dopamine system, and the development of stereotypic movements. Some human studies have supported this model. In one study, individuals with stereotypic movements had lower plasma homovanillic acid levels, a metabolite of dopamine and thus a marker of lower dopamine levels (Lewis et al. 1996). In addition, adults with stereotypic movements have decreased blink rates and greater motor slowness than matched controls, both of which have been associated with decreased dopamine system functioning (Bodfish et al. 1995, Lewis et al. 1996).

Serotonin has been studied in mental retardation and autism since the 1950s. Increased platelet uptake of serotonin in people with autism has been associated with decreased 5-HT2 receptor binding and an increase in stereotyped and self-injurious behaviors. Treatment with serotonin reuptake inhibitors has been associated with decreased stereotypic behavior in people with autism. Acute tryptophan depletion causes an increase in stereotypic behaviors in individuals with autism (Cook and Leventhal 1996, Schroeder et al. 2001).

The opioid system has also been studied in conjunction with stereotypic movements and self-injurious behavior. Several studies show that between 30% and 70% of patients with self-injurious behavior have dysregulated endogenous opioid systems (Schroeder et al. 2001). Patients with both stereotypic behaviors and self-injurious behaviors were found to have elevated β-endorphin plasma levels (Sandman et al. 1990). This finding led to the hypotheses that stereotypic and self-injurious behavior has the function of either indicating increased pain tolerance or addiction to endogenous opioids (Schroeder et al. 2001).

A group of animal studies have proposed a coping function for stereotypic movements, examining corticosterone levels as a marker of arousal. Mittleman et al. (1991) induced stereotypic movements with amphetamines, and then measured corticosterone levels. Corticosterone was significantly lower in the animals that had more stereotypic movements, supporting the hypothesis that stereotypies serve a function of reducing stress. Nevertheless, other studies have seemed to give opposite results, including a study by Wurbel and Stauffacher (1996) which looked at corticosterone levels in mice with a stereotypy of gnawing wire. Results here showed no increase in corticosterone when the mice did not have access to gnawing. The evidence remains inconclusive on the biological aspects of the coping function of stereotypic movements.

Genetic Factors
Though little is known about the genetic factors affecting stereotypic movements, several genetic syndromes do predispose people to stereotypic movements and self-injurious behavior. These syndromes have unique mechanisms likely resulting in changes in the dopaminergic neurons and other changes leading to stereotypic movements.

Lesh-Nyhan Syndrome, for example, is associated with stereotyped self-biting that usually results in self-injury. The genetic mechanism here is indirect and not fully explicated. The genetic abnormality in Lesh-Nyhan is a dysfunctional enzyme, hypoxanthine-guanine-phosphoribosyl-transferase (HPRT). This leads to a buildup of purine, which results in an accumulation of uric acid in body fluids including cerebrospinal fluid. Positron emission tomography studies of patients with Lesh-Nyhan Syndrome show decreased numbers of dopamine transporters and decreased DOPA-decarboxylase. These findings indicate a reduction in dopaminergic neurons, possibly due to a loss of arborization. The stereotypic movements are then caused by abnormalities in the dopamine system, although other abnormalities probably also contribute to the self-injurious behavior (Schroeder et al. 2001).

Psychological Factors
Stereotypic movements may be understood as a form of operant behavior that is maintained and reinforced by consequences of the behavior. In addition, other factors may contribute to the timing and intensity of the behavior. For example, the behavior will be decreased in the presence of social stimulation. Stereotypic behavior is also decreased following strenuous exercise, although not following mild exercise (Rapp and Vollmer 2005b).

Stereotypic and self-injurious behaviors may develop and persist in the absence of stimulation. Functional analysis of stereotypic behavior shows it can be maintained by positive reinforcement (e.g., sensory stimulation), negative reinforcement (e.g., removal of an unpleasant physical stimulus), or some combination of social and nonsocial reinforcement (e.g., social positive and automatic reinforcement) (Rapp and Vollmer 2005b).

Social/Environmental Factors
Deprivation is the environmental factor most associated with stereotypic behavior. The self-stimulating effect of stereotypies has long been proposed as its function, thus explaining the increased prevalence of stereotypies in individuals living in institutions.

Treatment
There are many different treatments for Stereotypic Movement Disorder, including several classes of medications, as well as behavior plans and social interventions. In approaching treatment, the first step should be addressing the patient’s deprivation with social interventions, if possible. Behavioral treatments and medications can be used secondarily as needed for management of the patient’s symptoms.

Somatic Treatments
No medications have been approved by the Food and Drug Administration for the treatment of Stereotypic Movement Disorder. However, several classes of medication have shown some efficacy in treatment of this disorder.

Serotonin reuptake inhibitors have shown some efficacy in treating stereotypic movement disorders. A placebo-controlled trial of Clomipramine in 11 patients showed efficacy in 10 of them. These patients maintained a decrease in stereotypies even when the Clomipramine was discontinued (Rapp and Vollmer 2005a). The effect is
postulated to be due to a serotonin mechanism, as a study comparing clomipramine with desipramine and placebo showed clomipramine to be more effective in decreasing repetitive and compulsive behavior (Gordon 1992). Other evidence of serotonergic medications being effective is limited to case reports. Fluoxetine, Paroxetine, Citalopram, and Mirtazapine have been reported helpful in some case studies, but not consistently. One study, for example, showed fluoxetine and paroxetine were of no benefit in 40% of 37 adults with developmental disabilities. In this study, 25% of subjects had some deterioration, while 35% showed some reduction in perseverative and maladaptive behaviors (Branford et al. 1998). Other studies of selective serotonin reuptake inhibitors (SSRIs) have been equivocal at best, showing no clear benefit for antidepressants.

Antipsychotics are some of the most commonly prescribed drugs for people with mental retardation and behavioral problems. Antipsychotic medication was prescribed to 17−56% of the residents of group homes for mentally retarded people (King 2002). Studies and even case reports for stereotypic movements and self-injurious behaviors are sparse over the past decade, and previous studies were often seriously methodologically flawed. Despite widespread use of antipsychotics to treat stereotypes, they have limited evidence of efficacy and significant side effects, and some have suggested their use may not be appropriate (Rapp and Vollmer 2005b).

A few recent studies have provided modest support for use of antipsychotics. A pilot study of seven adults with severe mental retardation and stereotypic self-injurious behavior were given a 15-week trial of olanzapine. Three of the seven showed “clear improvement,” while one additional person showed marginal improvement (McDonough et al. 2000). In the Autism literature, there are some studies that show improvement in stereotypic and self-injurious behavior with risperidone (McDougle et. al. 2005, Hellings et al. 2001).

One study of Valproic Acid in treatment of stereotypic behavior in autistic children showed a significant reduction in the stereotypic behavior in 13 patients as measured by the Children's Yale-Brown Obsessive Compulsive Scale (C-YBOCS) (Hollander 2006).

Opioid receptor blockers have been used for the treatment of self-injurious behavior with some efficacy. About 80% of patients in controlled studies had some decrease in self-injurious behavior with Naltrexone, and 47% of patients had a 50% or greater decrease in their behaviors (Symons et al. 2004). Specific studies, however, have varied greatly, and all studies include a significant number of opioid-blocker nonresponders; even the responders have not had as dramatic a decrease in self-injurious behavior as the endogenous opioid model would predict (Symons et al. 2004).

Psychosocial Treatments

Behavioral therapies have been used to treat stereotypic and self-injurious behaviors (Clinical Vignette 1). Because most stereotypic movements are automatically reinforced, interventions involving environmental enrichment, differential reinforcement, and punishment were behavioral techniques that at least temporarily decreased stereotypic movements. Much work has been done in this area and the results are often quite successful (Rapp and Vollmer 2005b).

Clinical Vignette 1

Gina, a 42-month-old female, was brought in by her foster mother at the suggestion of the day-care center staff. During unstructured times in day care, Gina gets on her hands and knees and rocked back and forth vigorously. She did this for minutes at a time, and continued until her teacher physically stopped her. While engaging in this rocking behavior, Gina did not play and had to be physically redirected repeatedly. Neither staff at the center nor the foster mother understood why she did this, and they were worried that the intensity of this body rocking was so high that she might hurt herself. In fact, she had bruise and abrasions on her knees.

Gina had been with this foster family for the past 7 months. She lived with her biological mother prior to that. Gina’s biological mother was not around much and left Gina and her 5-year-old brother with other family members and friends for days and even weeks at a time. Usually, Gina was put in the family room with the television on and left for hours at a time. Eventually, she was removed from her home because she was missing meals and her pediatrician diagnosed failure to thrive. Gina had been doing well with her foster family. They were providing consistent care and plenty of structure and stimulation. Initially, they had observed Gina rocking back and forth in a sitting position, but immediately attended to this behavior, providing her social stimulation and extra structure at times they noticed she engaged in these behaviors. Within a couple of months, these behaviors had stopped at home. The day care center provided structure and stimulation during the morning, but the afternoon staff was less skilled. It was during unstructured times in the afternoons that Gina’s behaviors became problematic. Gina was switched to another class in the afternoons, and her body rocking extinguished over the next several months.

REACTIVE ATTACHMENT DISORDER

Although social abnormalities in young children raised in abnormal environments have been described for many years, it was not until the publication of DSM-III (American Psychiatric Association 1980) that RAD appeared in psychiatric nosologies. The disorder described aberrant social behaviors in young children that were believed to derive from being reared in caregiving environments lacking in species typical nurturance and stimulation, such as in instances of maltreatment or institutional rearing. Subsequent to the original description of the disorder, the criteria have been revised to include two major types of abnormalities. These include an emotional withdrawn/inhibited type and an indiscriminately social/disinhibited pattern.

Despite descriptive studies of social abnormalities in deprived and maltreated children dating back more than half a century, systematic research on RAD has appeared only since the late 1990s. Nevertheless, findings to date are reasonably consistent about most features of the disorder (Zeanah and Smyke, in press).

Diagnosis

Definition and Diagnostic Features

According to DSM-IV-TR (American Psychiatric Association 1999), RAD is a disturbance in social
relatedness that is apparent across most developmental contexts. It appears in the first 5 years of life, and it must be distinguished from pervasive developmental disorders. That is, presence of a pervasive developmental disorder precludes the diagnosis. Two clinical patterns are apparent, an emotionally withdrawn/inhibited and an indiscriminately social/disinhibited type. These abnormal behaviors must be due to pathogenic care that the child has received.

Assessment
As with most other disorders of early childhood, RAD is best assessed through a combination of interviewing and direct-behavioral observation. A detailed history of the child’s caregiving experiences is important in order to establish that deficiencies were sufficient to account for the child’s social abnormalities. Therefore, details of the child’s caregiving history, with attention to neglect, changes in primary caregiving relationships, or significant losses of primary caregivers should be determined.

Structured interviews may be used to inquire about specific signs of the disorder (Smyke et al. 2002, Zeanah et al. 2004, Zeanah et al. 2005), and often are used to make the diagnosis. Standardized observational procedures that elicit the child’s responses to familiar and unfamiliar caregivers in order to distinguish between the child’s responses to putative attachment figures and to unfamiliar adults have been used in research and also may be useful in clinical settings (Boris et al. 2004, Zeanah et al. 2005).

Interviews and observations should include questioning about the child having one or more adults from whom he or she seeks comfort, reassurance, nurturing, and protection, particularly, in times of distress. In addition, failing to use the attachment figure for comfort, as occurs in the emotionally withdrawn/inhibited pattern, and exhibiting overly familiar behaviors with unfamiliar adults, as occurs in the indiscriminate/disinhibited pattern should be identified.

The clinical examination provides an opportunity to observe and stimulate attachment behaviors. The child’s reaction on first meeting the interviewer (a stranger) can provide information about how a child references and/or seeks comfort from a caregiver in the context of a new person and setting. In addition, asking a parent to leave the room for a brief separation from the child can activate the child’s attachment system and provide valuable information about how a child uses a parent upon reunion. Multiple observations and agreement between historical information and directly observed behaviors increase confidence in the diagnostic findings.

For a number of years, standardized observations of attachment behaviors were studied for assessment of attachment classifications rather than used diagnostically to assess RAD. However, a clinical assessment of attachment involving a stranger, separations and reunions, and the introduction of a robot as a mildly distressing stimulus also has been used reliably to diagnosis attachment disorders in a clinical context (Boris et al. 2004). The use of standardized procedures provides the clinician the opportunity to observe children’s patterns of attachment behaviors in a consistent manner, reducing the influence of other variables.

Epidemiology
Though epidemiologic data are limited, RAD is a rare disorder. In a study of 300 2–5-year-old children recruited from pediatric clinics in Durham, North Carolina, Egger et al. (2006) found no cases of RAD. Because pathogenic care is required to make the diagnosis, only children with histories of severe deprivation, such as maltreated children and those raised in institutions are eligible. Even in high-risk groups, the diagnosis is uncommon. For example, in a study of currently and formerly institutionalized children in Bucharest, Romania, at 54 months of age, fewer than a third of the children met criteria for RAD (Zeanah and Smyke, in press).

Comorbidity
There are no studies to date of comorbidity in RAD. Nevertheless, reasonable speculation is possible given what is known about the etiology of the disorder. Because of the conditions known to give rise to RAD, namely maltreatment and institutional deprivation, other disorders known to arise in similar conditions of risk may co-occur. Chief among these is developmental delays, particularly, mental retardation and language disorders. In addition, because physical abuse may co-occur with neglect, Posttraumatic Stress Disorder (PTSD) has been reported to co-occur with the emotionally withdrawn/inhibited type of RAD (Hinshaw-Fuselier et al. 1999).

Attention Deficit Hyperactivity Disorder (ADHD) also is known to be overrepresented among children raised in institutions, and it is possible that the social impulsivity that occurs in the emotionally withdrawn inhibited type of RAD co-occurs with the more cognitive and behavioral impulsivity that occurs in ADHD. This has not been examined systematically, but it remains one of the important questions about the disorder.

Course
Though relevant data remain scarce, findings to date suggest that the emotionally withdrawn/inhibited and the indiscriminately social types of RAD have different courses over time.

Only one longitudinal study has examined the course of the emotionally withdrawn type of RAD (Zeanah and Smyke, in press). In the Bucharest Early Intervention Project (BEIP) (Zeanah et al. 2003), young children living in institutions were randomly assigned to either continued institutional care or to removal from institutions and placement in foster care. The children in these two groups were followed from 2–4 years at regular intervals. In the institutionalized group, signs of the emotionally withdrawn/inhibited type of RAD persisted, but in young children placed with foster families, signs of the disorder disappeared within a few weeks to a few months (Zeanah and Smyke, in press). Although data are limited, to date no one has shown that formation of attachment is precluded, suggesting that the emotionally withdrawn/inhibited pattern of RAD remains responsive to intervention.

In contrast, several studies have demonstrated that the indiscriminate social/disinhibited type of RAD is one of the most persistent social abnormalities in young children raised in institutions. Even following adoption or placement in foster care, signs of indiscriminate/disinhibited RAD may persist.
for years (Chisholm 1998, Hodges and Tizard 1989, Rutter et al., in press; Zeanah and Smyke, in press). In the BEIP, young children in foster care had some reduction in signs of indiscriminate behavior, but this was primarily in those who had received the intervention when they were younger. These data suggest that for some children, there may be a critical period after which amelioration of the indiscriminately social/disinhibited pattern becomes far more difficult.

**Differential Diagnosis**

When considering a diagnosis of the emotionally withdrawn inhibited type of RAD, one must consider mental retardation and autistic spectrum disorders in the differential diagnosis. Most children with RAD will demonstrate significant concurrent developmental delays, but this may be distinguished from children who have solely delayed development. Focused attachment occurs in typically developing children at 7–9 months of age. Therefore, as long as the child has a cognitive age of at least 10 months, one may distinguish the emotionally withdrawn/inhibited type of RAD from mental retardation because in the former attachment behaviors are either absent, quite limited or aberrant. In mental retardation, the child has attachment behaviors readily discernible. RAD should not be diagnosed in children younger than 10 months of age because infants are not expected to manifest focused attachment behaviors much prior to that. The emotionally withdrawn/inhibited type may not be diagnosed if the child meets criteria for autism or pervasive developmental disorder not otherwise specified. RAD may be distinguished from autism in that in the latter there is a selective impairment in pretend play and a selective impairment in the initiation and response to joint attention, that is, the shared focus on an object of interest; neither of these impairments is present in RAD. In addition, although children with RAD often have stereotypes, they do not exhibit the kind of interest in restricted, repetitive interests and behaviors seen in children with pervasive developmental disorders.

The indiscriminately social/disinhibited type of RAD must be distinguished from nondisordered children with ADHD. The former distinction is guided by detailed questioning, by assessing impairment, and by experience of the evaluator, as there are no clearly identified cut off scores on standardized measures. Highly sociable children may be inclined to engage readily with unfamiliar adults, but they are probably not as willing to leave readily with a stranger, as has been reported for children with the indiscriminate/disinhibited type of RAD. Indiscriminate/disinhibited RAD may be distinguished from ADHD because the impulsivity in RAD is limited to social situations and because there is no reason for the child to demonstrate hyperactivity or distractibility.

**Differences in Presentation**

There are no known effects of gender or culture related to the presentation or prevalence of RAD. Age of onset is specified as within the first 5 years of life, but most likely the disorder is present from the latter part of the first year of life. Only one study has examined indiscriminate behavior in children placed in institutions after the first 3 years of life. No indiscriminate behavior was detected in young children who entered institutional care later following initial home rearing (Wolkind 1974).

**Etiology**

Unlike most DSM-IV-TR disorders, the etiology of RAD is specified in the criteria. The social abnormalities must be due to pathogenic care that the child received. Although pathogenic care is not described, examples are children who have limited opportunities to form selective attachments, such as those who experience frequent foster placement or institutional rearing. A consensus is that the key ingredient of pathogenic care related to the development of RAD is social neglect. What remains unclear is why two distinctive subtypes of RAD arise in similar conditions of risk but are phenomenologically different and have different courses and correlates.

**Genetic and Neurobiological Factors**

There are no known genetic risk factors for RAD. Nevertheless, because most children in socially-deprived environments do not develop RAD, an unresolved question is whether biological differences, including genetic polymorphisms, may confer vulnerability or risk to children experiencing severe deprivation. This has yet to be explored.

An intriguing finding possibly related to the indiscriminate/disinhibited type of RAD derives from work on Williams Syndrome, a microdeletion syndrome of the 7th chromosome. In addition to cognitive delays and physical abnormalities such as facial dysmorphology and supravalvular aortic stenosis, children with Williams Syndrome also demonstrate high levels of indiscriminate behavior, despite having no histories of deprivation (Jones et al. 2000). The phenotypic similarities raise questions about a specific genetic vulnerability to RAD.

There have been no direct studies of possible neurobiological contributors to RAD. Nevertheless, children raised in institutions, an environment known to increase risk for RAD, also have been shown to have long-term disturbances in cortisol metabolism (Gunnar and Vazquez 2006) and in brain functioning (Chugani et al. 2001). Nevertheless, the direct association of signs of RAD and these neurobiological abnormalities remains to be explored.

**Social/Environmental Factors**

RAD is one of the few disorders in DSM-IV-TR (American Psychiatric Association 1999) that includes the etiology as a criterion for diagnosis. Specifically, pathogenic care is supposed to account for the signs and symptoms of abnormal attachment and social behaviors seen in the disorder. Extreme caregiving environments, such as being raised in institutions or in conditions of social neglect are necessary for the disorder to occur. In fact, signs of the disorder are readily apparent in young children being raised in institutions (Smyke et al. 2002, Zeanah et al. 2005) and in maltreated children (Boris et al. 2004, Zeanah et al. 2004).

Within institutional settings, the emotionally withdrawn/inhibited pattern of RAD has been associated with quality of the caregiving that the child received (Zeanah et al. 2005). With regard to the indiscriminately social/disinhibited pattern, however, children adopted out of institutions show indiscriminate behavior proportionate to the degree
of deprivation they experienced, as defined by length of
time they were institutionalized (O’Connor et al. 2003). On
the other hand, this type of RAD has not been associated
with the quality of care the child received in an institutional
setting.

Other than the indiscriminate behavior described in
Williams Syndrome (Jones et al. 2000) and in fetal alcohol
syndrome (FAS) (Jacobson and Jacobson 2003, no cases of
children exhibiting signs of RAD have been described in the
absence of a history of severe neglect. There have been no
systematic studies of signs of indiscriminate behavior in FAS,
though this is an important area to examine because of the
likely overlap of social neglect in children who experienced
significant prenatal alcohol exposure. Similarities in the
presentation of children with Williams Syndrome and RAD
underscores the importance of the pathogenic care criterion
as a distinguishing feature of RAD.

Treatment
Despite limited data, the guiding principle of treatment of
RAD is that enhancing the caregiving environment of the
child leads to elimination of signs of disordered attachment
behavior (American Academy of Child and Adolescent
Psychiatry 2005). To date, there are a number of case reports
demonstrating just that (Hinshaw-Fuselier et al. 1999,

The primary goal of treatment for the emotionally
withdrawn/inhibited type of RAD is creating the possibility
for the child to develop a focused attachment relationship to
a primary caregiver. Ordinarily, this happens quickly once
a child is in a reasonably typical caregiving environment.
Attachment behaviors in young children placed into foster
care, for example, begin to develop within days of initial
placement (Stovall and Dozier 2000).

The goal for treatment of the indiscriminate disinhibited
type of RAD is to increase the child’s reliance on attachment
figures and decrease their engagement with unfamiliar
adults. Clinicians often advise that adoptive families limit the
contacts of children adopted out of institutions for a period
of several months, in order to give the child an opportunity
to form selective attachments to them and to reduce the
confusion of transitioning from an institutional setting to
a family. There are, however, no studies that have addressed
this advice. Indeed, from studies of children adopted out
of institutions, long-term stability of indiscriminate/
disinhibited behavior is clear (Chisholm 1998, Rutter et al.,
in press).

No medications are indicated for RAD. Somatic
treatments are used only to treat co-morbid disorders. The
disorder results from atypical caregiving environments and
may be ameliorated by enhanced caregiving relationships.

Caregiver characteristics and behaviors known to
foster secure attachments include knowing and valuing the
child as an individual, being sensitive and responsive to
the child’s needs, and placing the child’s needs ahead of
their own needs (Clinical Vignette 2). These are the
characteristics and behaviors that clinicians want to create.
Two approaches known to enhance attachment promoting
behaviors in caregivers include showing mothers videotapes
of sensitive caregiving and coaching them about how to
be more sensitive with their infants (van den Boom 1994
and Circle of Security (Hoffman et al. 2007), a group-based
intervention designed to teach caregivers about their own
emotional responses to their children and to help them
recognize when young children misjudge them about their
needs. Neither of these has yet been applied to children
diagnosed with RAD, however. Studies of treatment of
RAD are urgently needed to reduce morbidity and enhance
social adaptation in the child.

Lindsey was a 41-month-old girl who was removed from
her mother at age 32 months and placed in foster care.
Before that, she had a history of neglect and witnessing
extensive partner violence between her mother and
mother’s boyfriend. She was dismissed from her childcare
center for spitting, hitting, biting, and having a “demonic
look” earlier in the year. At the time she came into care,
Lindsey did not check back with her foster mother in
unfamiliar settings, showed affection towards total
strangers, and her foster mother reported having to hold
her hand in public settings (such as the mall) to prevent her
from “wandering off” with strangers. This caused her foster
mother considerable worry and restricted the number of
times she was willing take Lindsey out in public.

When seen for evaluation, Lindsey was active, running,
climbing, and doing summersaults, repeatedly calling
attention to herself. Despite her foster mother’s
admonitions, she ran into the offices of other clinicians
several times, and she approached and tried to kiss
several adults in the waiting area. She walked into
the receptionist’s area and linked her arm around the
receptionist’s arm. In the office, she made a show of falling
down and stating she was hurt, expressing the desire to be
rescued.

A behavioral plan was implemented to assist her foster
mother in managing Lindsey’s behavior. Her foster mother
was advised to restrict Lindsey’s contact with unfamiliar
adults and to talk with her about appropriate behavior
with strangers. In a follow-up three months later, the foster
mother reported that in a new daycare setting that was
warmer but more structured than the initial setting,
Lindsey’s behavior settled down considerably. Her
eagerness to hug and kiss strangers was reported to be
declining, but she continued to approach unfamiliar adults.

This chapter reviews dementia, delirium, amnestic, and other cognitive disorders. Traditionally, these conditions have been classified as organic brain disorders to distinguish them from such diseases as schizophrenia, mania, and major depressive disorder, the so-called functional disorders. With the publication of the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR), the distinction between functional and organic disorders was eliminated. Significant research into the neurobiological aspects of psychiatric disorders and the utilization of sophisticated neurodiagnostic tests such as positron emission tomographic scanning in schizophrenics led to the inescapable conclusion that every psychiatric condition has a biological component. Thus the term functional became obsolete and even misleading.

The conditions formerly called organic are classified in DSM-IV-TR into three groupings: (1) delirium, dementia, and amnestic and other cognitive disorders; (2) mental disorders due to a general medical condition; and (3) substance-related disorders (First 1994). Delirium, dementia, and amnestic disorders are classified as cognitive because they feature impairment in such parameters as memory, language, or attention as a cardinal symptom. Each of these three major cognitive disorders is subdivided into categories that ascribe the etiology of the disorder to a general medical condition, the persisting effects of a substance, or multiple etiologies. A “not otherwise specified” category is included for each disorder (First 1994).

In the case of delirium, the primary disturbance is in the level of consciousness with associated impairments in orientation, memory, judgment, and attention. Dementia features cognitive deficits in memory, language, and intellect. The amnestic disorder is characterized by impairment in memory in the absence of clouded consciousness or other noteworthy cognitive dysfunction. In general, the cognitive disorders should represent a decline from a previous higher level of function, of either acute (delirium) or insidious (dementia) onset, and should interfere with the patient’s social or occupational functioning (First 1994).
Dementia is defined in DSM-IV-TR as a series of disorders characterized by the development of multiple cognitive deficits (including memory impairment) that are due to the direct physiological effects of a general medical condition, the persisting effects of a substance, or multiple etiologies (e.g., the combined effects of a metabolic and a degenerative disorder) (First 1994). The disorders constituting the dementias share a common symptom presentation and are identified and classified on the basis of etiology. The cognitive deficits exhibited in these disorders must be of sufficient severity to interfere with either occupational functioning or the individual’s usual social activities or relationships. In addition, the observed deficits must represent a decline from a higher level of function and not be the consequence of a delirium. A delirium can be superimposed on a dementia often exhibit impairments in language, recognition, object naming, and motor skills. Aphasia is an abnormality of language that often occurs in vascular dementias involving the dominant hemisphere. Because this hemisphere controls verbal, written, and sign language, these patients may have significant problems interacting with people in

Clinical Features
Essential to the diagnosis of dementia is the presence of cognitive deficits that include memory impairment and at least one of the following abnormalities of cognition: aphasia, agnosia, apraxia, or a disturbance in executive function (First 1994).

Memory function is divided into three compartments that can easily be evaluated during a Mental Status Examination. These are immediate recall (primary memory), recent (secondary) memory, and remote (tertiary memory). Primary memory is characterized by a limited capacity, rapid accessibility, and a duration of seconds to minutes (Karp 1984). The anatomical site of destruction of primary memory is the reticular activating system, and the principal activity of the primary memory is the registration of new information. Primary memory is generally tested by asking the individual to repeat immediately a series of numbers in the order given. Because primary memory testing measures such parameters as attention, concentration, and ability to follow instructions, the results are often abnormal for the demented patient. This loss of ability to register new information accounts in part for the confusion and frustration the demented patient feels when confronted with unexpected changes in daily routine.

Secondary memory has a much larger capacity than primary memory, a duration of minutes to years, and relatively slow accessibility. The anatomical site of dysfunction for secondary memory is the limbic system, and individuals with a lesion in this area may have little difficulty repeating digits immediately, but show rapid decay of these new memories. In minutes, the patient with limbic involvement may be totally unable to recall the digits or even remember that a test has been administered (Karp 1984). Thus, secondary memory represents the retention and recall of information that has been previously registered by primary memory. Clinically, secondary memory is tested by having the individual repeat three objects after having been distracted (usually by the examiner’s continuation of the Mental Status Examination) for 3–5 min. Like primary memory, secondary recall is often impaired in dementia. Patients with an early or mild dementia may be able to retrieve memories if given some sort of clue, such as “…one of the objects you missed was a color.” Giving clues to the demented patient with a primary memory loss is pointless, because the memories were never registered. Wernicke-Korsakoff syndrome is an example of a condition in which primary memory may be intact while secondary recall is impaired.

Tertiary (remote) memory has a capacity that is probably unlimited, and such memories are often permanently retained. Access to tertiary memories is rapid, and the anatomical dysfunction in tertiary memory loss is in the association cortex (Karp 1984). In the early stages of dementia, tertiary memory is generally intact. It is tested by instructing the individual to remember personal information or past material. The personal significance of the information often influences the patient’s ability to remember it. For example, a woman who worked for many years as a seamstress might remember many details related to that occupation, but could not recall the names of past presidents or three large cities in the United States. Thus, a patient’s inability to remember highly significant past material is an ominous finding. Collateral data from informants is essential in the proper assessment of memory function. In summary, primary and secondary memories are most likely to be impaired in dementia, with tertiary memory often spared until late in the course of the disease.

In addition to defects in memory, patients with dementia often exhibit impairments in language, recognition, object naming, and motor skills. Aphasia is an abnormality of language that often occurs in vascular dementias involving the dominant hemisphere. Because this hemisphere controls verbal, written, and sign language, these patients may have significant problems interacting with people in
their environment. Patients with dementia and aphasia may exhibit paucity of speech, poor articulation, and a telegraphic pattern of speech (nonfluent, Broca's aphasia). This form of aphasia generally involves the middle cerebral artery with resultant paresis of the right arm and lower face (Henderson 1990). Despite faulty communication skills, patients with dementia with nonfluent aphasia have normal comprehension and awareness of their language impairment. As a result, such patients often present with significant depression, anxiety, and frustration.

By contrast, patients with dementia with fluent (Wernicke's) aphasia may be quite verbose and articulate, but much of the language is nonsensical and rife with such paraphasias as neologisms and clang (rhyming) associations. Whereas nonfluent aphasia are usually associated with discrete lesions, fluent aphasia can result from such diffuse conditions as dementia of the Alzheimer type. More commonly, fluent aphasia occur in conjunction with vascular dementia secondary to temporal or parietal lobe CVA. Because the demented patients with fluent aphasia have impaired comprehension, they may seem apathetic and unconcerned with their language deficits, if they are in fact aware of them at all. They do not generally display the emotional distress of patients with dementia and nonfluent aphasia (Table 51–2).

The two most common forms of apraxia in demented patients are ideational and gait apraxia. Ideational apraxia is the inability to perform motor activities that require sequential steps and results from a lesion involving both frontal lobes or the complete cerebrum. Gait apraxia, often seen in such conditions as normal-pressure hydrocephalus, is the inability to perform various motions of ambulation. It also results from conditions that diffusely affect the cerebrum.

Impairment of executive function is the inability to think abstractly, plan, initiate, and end complex behavior. On Mental Status Examination, patients with dementia display problems coping with new tasks. Such activities as subtracting serial sevens may be impaired.

Obviously, aphasia, agnosia, apraxia, and impairment of executive function can seriously impede the demented patients' ability to interact with their environment. An appropriate Mental Status Examination of the patient with suspected dementia should include screening for the presence of these abnormalities.

### Mental Status Examination

The findings on the Mental Status Examination vary depending on the etiology of the dementia. Some common abnormalities have been discussed previously (see earlier section on clinical features). In general, symptoms seen on the Mental Status Examination, whatever the etiology, are related to the location and extent of brain injury, individual adaptation to the dysfunction, premorbid coping skills and psychopathology, and concurrent medical illness (Slaby and Erle 1993).

Disturbance of memory, especially primary and secondary memory, is the most significant abnormality. Confabulation may be present as the patient attempts to minimize the memory impairment. Disorientation and altered levels of consciousness may occur, but are generally not seen in the early stages of dementia uncomplicated by delirium. Affect may be affected as in the masked facies of Parkinson's disease and the expansive affect and labile mood of pseudobulbar palsy after cerebral injury. The affect of patients with hepatic encephalopathy is often described as blunted and apathetic. Lack of inhibition leading to such behavior as exposing oneself is common, and some conditions such as tertiary syphilis and untoward effects of some medication can precipitate mania. The Mental Status Examination, in conjunction with a complete medical history from the patient and informants and an adequate physical examination, is essential in the evaluation and differential diagnosis of dementia (Table 51–3).

### Physical and Neurological Examinations in Dementia

The physical examination may offer clues to the etiology of the dementia; however, in the elderly, one must be aware of the normal changes associated with aging and differentiate them from signs of dementia. Often the specific physical examination findings indicate the area of the central nervous system affected by the etiological process. Parietal lobe dysfunction is suggested by such symptoms as astereognosis, constructional apraxia, anosognosia, and problems with two-point discrimination (Kaufman 1990a). The dominant hemisphere parietal lobe is also involved in Gerstmann's syndrome, which includes agraphia, acalculia, finger agnosia, and right–left confusion.

Patients with dementia may also lose their ability to recognize. Agnosia is a feature of a dominant hemisphere lesion and involves altered perception in which, despite normal sensations, intellect, and language, the patient cannot recognize objects. This is in contrast to aphasia in which the patient with dementia may not be able to name objects, but can recognize them (Berg et al. 1994). The type of agnosia depends on the area of the sensory cortex that is involved. Some demented patients with severe visual agnosia cannot name objects presented, match them to samples, or point to objects named by the examiner. Other patients may present with auditory agnosia and be unable to localize or distinguish such sounds as the ringing of a telephone. A minority of demented patients may exhibit astereognosis, inability to identify an object by palpation.

Demented patients may also lose their ability to carry out selected motor activities despite intact motor abilities, sensory function, and comprehension of the assigned task (apraxia). Affected patients cannot perform such activities as brushing their teeth, chewing food, or waving good-bye when asked to do so (Kaufman 1990a).
Reflex changes such as hyperactive deep tendon reflexes, Babinski’s reflex, and hyperactive jaw jerk are indicative of cerebral injury. However, primitive reflexes such as the palmomental reflex, which occurs in 60% of normal elderly people, and the snout reflex seen in a third of elderly patients are not diagnostically reliable for dementia (Wolfson and Katzman 1983).

Ocular findings such as nystagmus (as in brain stem lesions), ophthalmoplegia (Wernicke-Korsakoff syndrome), anisocoria, papilledema (hypertensive encephalopathy), cortical blindness (Anton’s syndrome), visual field losses (CVA hemianopia), Kayser–Fleischer rings (Wilson’s disease), and Argyll Robertson pupils (syphilis, diabetic retinopathy) can offer valuable clues to the etiology of the cognitive deficit (Victor and Adams 1974).

Movement disorders including tremors (Parkinson’s disease, drug intoxication, cerebellar dysfunction, Wilson’s disease), chorea (Huntington’s disease, other basal ganglia lesions), myoclonus (subacute sclerosing panencephalitis, Creutzfeldt-Jakob disease, Alzheimer disease, anoxia), and asterixis (hepatic disease, uremia, hypoxia, carbon dioxide retention) should be noted.

Gait disturbances, principally apraxia (normal-pressure hydrocephalus, inhant abuse, cerebellar dysfunction) and peripheral neuropathy (Korsakoff’s syndrome, neurosyphilis, heavy metal intoxication, solvent abuse, isoniazid or phenytoin toxicity, vitamin deficiencies, and HIV spectrum illnesses), are also common in dementia. Extrapyramidal symptoms in the absence of antipsychotics may indicate substance abuse, especially phencyclidine abuse, or basal ganglia disease. Although the many and varied physical findings of dementia are too numerous to mention here, it should be obvious that the physical examination is an invaluable tool in the assessment of dementia (Table 51–4).

### Associated Features and Behavior

In addition to the diagnostic features already mentioned, patients with dementia display other identifying features that often prove problematic. Poor insight and poor judgment are common in dementia and often cause patients to engage in potentially dangerous activities or make unrealistic and grandiose plans for the future. Visual–spatial functioning may be impaired, and if patients have the ability to construct a plan and carry it out, suicide attempts can occur. More common is unintentional self-harm resulting from carelessness, undue familiarity with strangers, and disregard for the accepted rules of conduct.

Emotional lability, as seen in pseudobulbar palsy after cerebral injury, can be particularly frustrating for caregivers, as are occasional psychotic features such as delusions and hallucinations. Changes in their environment and daily routine can be particularly distressing for demented patients, and their frustration can be manifested by violent behavior.

### Epidemiology

The prevalence of dementias is not precisely known. Estimates vary depending on the age range of the population studied and whether the individuals sampled were in the general community, acute care facilities, or long-term nursing institutions. A review of 47 surveys of dementia conducted between 1934 and 1985 indicated that dementia increased exponentially, doubling every 5 years up to age 95 years, and that this condition was equally distributed among men and women, with Alzheimer’s dementia (AD) much more common in women (Slaby and Erle 1993). Other dementias such as those related to cerebrovascular diseases are more common in males, so while overall the distribution of dementia is equal between men and women, some types are more common in men and others more commonly diagnosed in women. A National Institute of
Mental Health Multisite Epidemiological Catchment Area study revealed a 6-month prevalence rate for mild dementia of 11.5% to 18.4% for persons older than 65 years living in the community (Kallmann 1989). The rate for severe dementia was higher for the institutionalized elderly. Fifteen percent of the elderly in retirement communities, 30% of nursing home residents, and 54% of the elderly in state hospitals were severely demented (Cummings and Benson 1983).

Studies suggest that the fastest growing segment of the US population consists of persons older than the age of 85 years, 15% of whom are demented (Henderson 1990). Half of the US population currently lives to the age of 75 years and one quarter live to the age of 85 (Berg et al. 1994). A study of 2000 consecutive admissions to a general medical hospital revealed that 9% were demented and, of those, 41% were also delirious on admission (Erkinjuntti et al. 1986).

The cost of providing care for demented patients exceeds $100 billion annually (about 10% of all health care expenditures) and the average cost to families in 1990 was $18,000 a year (Berg et al. 1994).

Course

The course of a particular dementia is influenced by its etiology. Although historically the dementias have been considered progressive and irreversible, there is, in fact, significant variation in the course of individual dementias. The disorder can be progressive, static, or remitting (First 1994). In addition to the etiology, factors that influence the course of the dementia include (1) the time span between the onset and the initiation of prescribed treatment, (2) the degree of reversibility of the particular dementia, (3) the presence of comorbid psychiatric disorders, and (4) the level of psychosocial support.

The previous distinction between treatable and untreatable dementias has been replaced by the concepts of reversible, irreversible, and arrestable dementias. Most reversible cases of dementia are associated with shorter duration of symptoms, mild cognitive impairment, and superimposed delirium. Specifically, the dementias caused by drugs, depression, and metabolic disorders are most likely to be reversible. Other conditions such as normal pressure hydrocephalus, subdural hematomas, and tertiary syphilis are more commonly arrestable.

Although potentially reversible dementias should be aggressively investigated, in reality, only 8% of dementias are partially reversible and about 3% fully reversible (Kaufman 1990b). There is some evidence to suggest that early treatment of demented patients, particularly those with Alzheimer’s type with such agents as donepezil (Aricept) which acts as an inhibitor of acetylcholinesterase, and galantamine (Reminyl) may slow the rate of progression of the dementia although some investigators doubt the ability of these agents to slow the rate of progression.

Differential Diagnosis

Memory impairment occurs in a variety of conditions including delirium, amnestic disorders, and depression (First 1994). In delirium, the onset of altered memory is acute and the pattern typically fluctuates (waxing and waning) with increased proclivity for confusion during the night. Delirium is more likely to feature autonomic hyperactivity and alterations in level of consciousness. In some cases a dementia can have a superimposed delirium (Figure 51–1).

Patients with major depression often complain of lapses in memory and judgment, poor concentration, and seemingly diminished intellectual capacity. Often these symptoms are mistakenly diagnosed as dementia, especially in elderly populations. A thorough medical history and Mental Status Examination focusing on such symptoms as hopelessness, crying episodes, and unrealistic guilt in conjunction with a family history can be diagnostically beneficial. The term pseudodementia has been used to denote cognitive impairment secondary to a functional psychiatric disorder, most commonly depression (Korvath et al. 1989). In comparison with demented patients, those with depressive pseudodementia exhibit better insight regarding their cognitive dysfunction, are more likely to give “I don’t know” answers and may exhibit neurovegetative signs of depression. Pharmacological treatment of the depression should improve the cognitive dysfunction as well. Because of the rapid onset of their antidepressant action, the use of psychostimulants (methylphenidate, dextroamphetamine) to differentiate between dementia and pseudodementia has been advocated by some authors (Frierson et al. 1991). Some authors have proposed abandonment of the term pseudodementia, suggesting that most patients so diagnosed have both genuine dementia and a superimposed affective disorder (Figure 51–2).

An amnestic disorder also presents with a significant memory deficit, but without the other associated features such as aphasia, agnosia, and apraxia. If cognitive hyperactivity and alterations in level of consciousness. In some cases a dementia can have a superimposed delirium (Figure 51–1).

Patients with major depression often complain of lapses in memory and judgment, poor concentration, and seemingly diminished intellectual capacity. Often these symptoms are mistakenly diagnosed as dementia, especially in elderly populations. A thorough medical history and Mental Status Examination focusing on such symptoms as hopelessness, crying episodes, and unrealistic guilt in conjunction with a family history can be diagnostically beneficial. The term pseudodementia has been used to denote cognitive impairment secondary to a functional psychiatric disorder, most commonly depression (Korvath et al. 1989). In comparison with demented patients, those with depressive pseudodementia exhibit better insight regarding their cognitive dysfunction, are more likely to give “I don’t know” answers and may exhibit neurovegetative signs of depression. Pharmacological treatment of the depression should improve the cognitive dysfunction as well. Because of the rapid onset of their antidepressant action, the use of psychostimulants (methylphenidate, dextroamphetamine) to differentiate between dementia and pseudodementia has been advocated by some authors (Frierson et al. 1991). Some authors have proposed abandonment of the term pseudodementia, suggesting that most patients so diagnosed have both genuine dementia and a superimposed affective disorder (Figure 51–2).

An amnestic disorder also presents with a significant memory deficit, but without the other associated features such as aphasia, agnosia, and apraxia. If cognitive

Figure 51–1 Differentiation of delirium and dementia.
impairment occurs only in the context of drug use, substance intoxication or substance withdrawal is the appropriate diagnosis. Although mental retardation implies below average intellect and subsequent impairment in other areas of function, the onset is before 18 years of age and abnormalities of memory do not always occur. Mental retardation must be considered in the differential diagnosis of dementias of childhood and adolescence along with such disorders as Wilson’s disease (hepatolenticular degeneration), lead intoxication, subacute sclerosing panencephalitis, HIV spectrum disorders, and substance abuse, particularly abuse of inhalants.

Patients with schizophrenia may also exhibit a variety of cognitive abnormalities, but this condition also has an early onset, a distinctive constellation of symptoms, and does not result from a medical condition or the persisting effects of a substance. Factitious disorder must be distinguished from dementia. Unlike dementia, this condition presents with inconsistent symptoms that, although similar in some respects, are not totally consistent with those of a dementia. For example, a patient with Factitious Disorder with psychological symptoms (in this case dementia) might have equal impairment in all phases of memory, while patients with dementia usually have better remote than recent memory. Dementia must also be distinguished from benign senescence (normal aging). Only when such changes exceed the level of altered function to be expected for the patient’s age is the diagnosis of dementia warranted (First 1994).

Degenerative Causes of Dementia

Dementia of the Alzheimer Type

Historical Perspective

In 1906 Alois Alzheimer reported a case of presenile dementia in a 51-year-old woman who displayed progressive memory loss and disorientation. His presentation was published in Allgemeine Zeitschrift für Psychiatrie und Psychisch-Gerichtliche Medizin in 1907. His
### DSM-IV-TR Criteria

**Dementia of the Alzheimer Type**

A. The development of multiple cognitive deficits manifested by both

1. memory impairment (impaired ability to learn new information or to recall previously learned information)
2. one (or more) of the following cognitive disturbances:
   a. aphasia (language disturbance)
   b. apraxia (impaired ability to carry out motor activities despite intact motor function)
   c. agnosia (failure to recognize or identify objects despite intact sensory function)
   d. disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)

B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.

C. The course is characterized by gradual onset and continuing cognitive decline.

D. The cognitive deficits in criteria A1 and A2 are not due to any of the following:

1. other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
2. systemic conditions that are known to cause dementia (e.g., hypothyroidism, vitamin B12 or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
3. substance-induced conditions

E. The deficits do not occur exclusively during the course of a delirium.

F. The disturbance is not better accounted for by another Axis I disorder (e.g., major depressive disorder, schizophrenia).

**Code** based on type of onset and predominant features:

- With early onset: if onset is at age 65 years or below
  294.11 With delirium: if delirium is superimposed on the dementia
  294.12 With delusions: if delusions are the predominant feature
  294.13 With depressed mood: if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.
  294.10 Uncomplicated: if none of the above predominates in the current clinical presentation

- With late onset: if onset is after age 65 years
  294.3 With delirium: if delirium is superimposed on the dementia
  294.20 With delusions: if delusions are the predominant feature
  294.21 With depressed mood: if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.
  294.0 Uncomplicated: if none of the above predominates in the current clinical presentation

Specify if:

- With behavioral disturbance

**Coding note**: Also code 331.0 Alzheimer's disease on Axis III.

---

In summary, we are apparently confronted with a distinctive disease process. An increasing number of unusual diseases have been discovered during the past few years. These observations show that we should not be satisfied to take a clinically unclear case and, by making great efforts, fit it into one of the known disease categories. Undoubtedly, there are many more psychiatric diseases that are included in our textbooks. Often a subsequent histological examination would show the peculiarity of the case. Then gradually we would be able to separate individual diseases clinically from the large classes of diseases in our textbooks and define their clinical characteristics more precisely (Wilkins and Brody 1969).

Two years earlier, Alzheimer had written of miliary plaque formations that often appeared in the brains of patients with senile dementia (Bick 1994). He and his coworkers subsequently described neurofibrillary changes and granulovacuolar degeneration in senile and presenile dementia (Bick 1994). Almost 90 years later, Alzheimer's disease is the most common form of dementia and remains a major focus of scientific investigation.

**Epidemiology**

Alzheimer's disease is the most common cause of dementia, accounting for 55–65% of all cases (Korvath et al. 1989). There were fewer than 3 million causes in 1980, but the
Census Bureau predicted that there will be more than 10 million American citizens with Alzheimer's disease by the year 2050 (Evans 1990). Prevalence of the disease doubles with every 5 years between the ages of 65 and 85 years (Katzman and Kawas 1994). Some authors separate Alzheimer’s disease into senile and presenile forms, but the two disorders represent the same pathological process (Berg et al. 1994). Significantly, however, early-onset Alzheimer’s disease is associated with a more rapid course than later onset disease (Lezak 1983). The disease has a prevalence of 6–8% in individuals 65 years or older (Muralee et al. 2004).

Alzheimer’s disease affects women three times as often as men, for unknown reasons. Furthermore, at least one study suggests that dementia, including Alzheimer’s, is more common in black than in white American women. (Heyman et al. 1991) Comparison of population studies in diverse countries shows strikingly similar prevalence rates (Katzman and Kawas 1994).

Longitudinal studies have revealed the importance of family history as a risk factor; however, no consistent genetic pattern has been established. Nonetheless, the incidence of progressive dementias including Alzheimer’s in first-degree relatives older than 90 years approaches 50% (Korvath et al. 1989). For Alzheimer’s alone, the probability of developing dementia if a first-degree relative (parent or sibling) is afflicted is four times than of the general population, and if two or more first-degree relatives have the disease the risk is increased eightfold compared with a normal sample of US citizens (Katzman and Kawas 1994). Forty-three percent of monozygotic twins are concordant for the disorder, compared with only 8% of dizygotic twins (Berg et al. 1994).

In addition to age, gender, and family history, the presence of Down’s syndrome, a history of head trauma, and a low level of education have been proposed as risk factors. Most studies concur that individuals with trisomy (Lezak 1983) develop the features of AD by age 35 years; however, studies looking at the possibility that families with a member who has AD are more likely to produce offspring with Down’s syndrome have had inconclusive results (Burger and Vogel 1973). Significant head injury, as either a single incident or a chronic occurrence as in sports injuries, increases the risk of developing Alzheimer’s by a factor of 2 (Katzman and Kawas 1994). An uneducated person older than 75 years is about twice as likely to develop dementia as one who has 8 years or more schooling (Katzman and Kawas 1994). Risk factors found in some, but not all studies include myocardial ischemia in the elderly, birth to a mother older than age 40 years, and exposure to aluminum (Katzman and Kawas 1994). For a more detailed examination of risk factors in AD, please see *Alzheimer’s Disease*, edited by Terry and Colleagues (Terry et al. 1994).

**Pathology**

The etiology and pathogenesis of Alzheimer’s disease are unknown. Multiple agents and pathways are likely involved in this disorder (Markesbery and Ehmann 1994). Many hypotheses have been proposed regarding the cause and progression of Alzheimer’s disease including genetic factors, slow or unconventional viruses, defective membrane metabolism, endogenous toxins, autoimmune disorders, and neurotoxicity of such trace elements as aluminum and mercury (Markesbery and Ehmann 1994).
Alzheimer’s disease. Neurofibrillary tangles do not correlate with the severity of the dementia; however, the concentration of neuritic plaques is directly associated with the severity of the disease (Kaufman 1990a).

Neurochemically, the brains of patients with Alzheimer’s disease exhibit significant cholinergic abnormalities (Kaufman 1990b). There is a profound decrease in acetylcholine (Ach) in almost all patients, as well as decreased immunological activity of somatostatin- and corticotropin-releasing factors (Kaufman 1990b). The enzyme required for Ach synthesis, choline acetyltransferase, is also greatly reduced. Other studies suggest involvement of noradrenergic and serotoninergic systems in later onset disease and diminished γ-aminobutyric acid (GABA) (Kaufman 1990b). Specifically, the noradrenergic deficiencies seen in younger patients may be connected to changes in the locus ceruleus, and abnormalities of serotonin to effects on the raphe nuclei (Korvath et al. 1989). The serotoninergic neurons of the raphe nuclei in patients with Alzheimer’s disease contain 6–39 times as many neurofibrillary tangles as those of age-appropriate control subjects, and noradrenergic neurons from the locus ceruleus of patients with Alzheimer’s disease show neuronal loss of 40–80% (Korvath et al. 1989). Unfortunately, despite these observed neurochemical abnormalities, neurotransmitter-related treatment with cholinergic and GABergic agents has proved largely unsuccessful.

Although the involvement of cholinergic transmission along the hippocampus and nucleus basalis is essential to the ability to learn new information, it seems that many of the symptoms of Alzheimer’s disease are not explainable solely on the basis of cholinergic abnormalities. Thus, investigators have examined a number of other potential etiological or contributory agents.

Some researchers have investigated the role of B-amyloid protein in Alzheimer’s disease, and some assert that this material, a significant component of all plaques, is a major contributor to the neurodegenerative changes in the disease as both an initiator and a promotor of the disease (Cotman and Pike 1994). Supporting this assertion are genetic studies of families with inheritable forms of presenile dementia, which show that disease occurrence is linked to mutations involving B-amyloid-related systems (Kidd 1963). This hypothesis targets the protein found in senile plaques; other investigators have focused on the neurofibrillary tangles and the identification of a major component of its helical filament, the tau protein (Kidd 1963, Wisniewski et al. 1976). Specifically, these researchers analyzed the possibility that modification of tau protein, predominantly by phosphorylation, is an important feature of AD (Delacourte and Defossez 1986, Grundke-Igbal et al. 1986, Nukina and Ihara 1986).

Aluminum, the third most common element in the universe, is absorbed from the gastrointestinal tract, lungs, nasal passage, and skin (Ganrot 1986, Perl and Good 1987, Terry et al. 1994). Dollken (1897) first demonstrated that aluminum injected in rabbits produced degeneration of neurons. Scherp and Church (1937) reported various neurological abnormalities including nystagmus, ataxia, and death in rabbits 10–18 days after a single injection of aluminum. Klatzo et al. (1965) discovered neurofibrillary tangles in rabbits receiving intracerebral injections of aluminum. Crapper and Dalton (1972) reported increased aluminum in the brain of patients with Alzheimer’s disease, with about a quarter of such samples showing concentrations three standard deviations above the control values. Other studies of bulk brain aluminum in patients with Alzheimer’s disease have shown no such elevation (Markesbery and Ehmann 1994). The current consensus appears to be that although aluminum and other elements such as iron and mercury might accelerate neuronal degeneration in AD, these elements are not primary etiological agents.

The role of genetic factors in the development of AD has received increased attention as the role of the apolipoprotein E4 allele as a major genetic susceptibility risk factor has been confirmed by numerous studies (Katzman 1994). Corder et al. (1993) studied 234 members of 42 families with late-onset AD. Of 95 affected members, 80% had the E4 allele, compared with 26% in the general population (Corder et al. 1993). Furthermore, in these families, 91% of those homozygous for Er had developed Alzheimer’s disease by 80 years of age, evidence that the APOE e4 allele is causing these familial cases (Corder et al. 1993). In a study of 176 autopsy specimens of confirmed AD, Schmechel and coworkers in 1993 found that 65% of patients carried at least...
one apolipoprotein E e4 gene (Katzman 1994). Examination of all such studies indicates that between 25% and 40% of AD cases can be attributable to this marker, making its presence one of the most common risk factors yet discovered for AD (Corder et al. 1993, Katzman 1994).

Finally, several studies suggest that changes in membrane function, metabolism, and morphology are involved in the pathology of AD. Nonetheless, the basic molecular defect responsible for AD dementia has not been defined (Pettegrew et al. 1994).

The neuropathology of Alzheimer’s disease should be compared with the normal neuropathic effects of aging. These include the following:

1. The leptomeninges become more fibrotic and are more adherent to the brain surface with increased opacity.
2. The ventricles show slight to moderate enlargement that increases with the passage of time.
3. The distance between the dura and the brain is increased.
4. Sulci widen and gyri become narrower.
5. The number of neurons decreases slightly.
6. The weight of the brain decreases in the fourth and fifth decades, with significant decrease by the age of 80 years.
7. Neurofibrillary tangles and senile plaques occur in virtually every elderly individual by the 10th decade of life (Berg et al. 1994).

Laboratory and Radiological Findings

The role of laboratory determinations in the evaluation for AD is to exclude other causes of dementia, especially those that may prove reversible or arrestable. Before death, AD is largely a diagnosis of exclusion. Throughout the course of this disorder, laboratory values are essentially normal. Some nonspecific changes may occur, but electroencephalography and lumbar puncture are not diagnostic. As the disease progresses, computed tomography (CT) and magnetic resonance imaging (MRI) may show atrophy in the cerebral cortex and hydrocephalus ex vacuo (Figure 51–7). MRI may show nonspecific alteration of white matter (leukoariosis), and eventually the electroencephalogram (EEG) shows diffuse background slowing.

Pneumoencephalography has demonstrated enlarged ventricles and widening of cortical sulci in Alzheimer’s disease, and positron emission tomography in the later stages shows decreased cerebral oxygen and glucose metabolism in the frontal lobes. At present, in the workup of a patient with a slowly progressive dementia, a good family history and physical examination and laboratory and radiographic tests to rule out other causes of dementia are the most effective tools in the diagnosis of Alzheimer’s disease.

Clinical Features

The course and clinical features of AD parallel those discussed for dementia in general. Typically, the early course of AD is difficult to ascertain because the patient is usually an unreliable informant, and the early signs may be so subtle as to go unnoticed even by the patient’s closest associates (Karp 1984). These early features include impaired memory, difficulty with problem solving, preoccupation with long past events, decreased spontaneity, and an inability to respond to the environment with the patient’s usual speed and accuracy (Karp 1984). Patients may forget names, misplace household items, or forget what they were about to do. Often the individuals have insight into these memory deficits and occasionally convey their concerns to family members. Such responses as “You’re just getting older,” and “I do that sometimes myself” are common from those so informed, and as a result the patient becomes depressed, which can further affect cognitive functioning. Anomia, or difficulty with word finding, is common in this middle stage of Alzheimer’s disease. Eventually the patient develops schemes, word associations, and excuses (“I never was very good in math”) to assist in retention and cover up deficits. The patient may also employ family members as a surrogate memory (Karp 1984).

Because memory loss is usually most obvious for newly acquired material, the patient tries to avoid unfamiliar activities. Typically, the patient is seen by the physician when confusion, aggression, wandering, or some other socially undesirable behavior ensues. At that time, disorders of perception and language may appear. The patient often turns to a spouse to answer questions posed during the history taking. By this time the affected individual has lost insight into his or her dementia and abandons attempts to compensate for memory loss (Karp 1984). Finally, in the late stage of Alzheimer’s disease, physical and cognitive effects are marked. Disorders of gait, extremity paresis and paralysis, seizures, peripheral neuropathy, extrapyramidal signs, and urinary incontinence are seen, and the patient is often no longer ambulatory. The aimless wandering of the middle stage has been replaced by a mute, bedridden state and decorticate posture. Myoclonus occasionally occurs. Significantly, affective disturbances remain a distinct possibility throughout the course of the illness. AD progresses at a slow pace for 8–10 years to a state of complete helplessness.

Treatment

The two principles of management in AD are to treat what is treatable without aggravating existing symptoms and to support caregivers, who are also victims of this disease.
Despite the significant decrease in ACh and choline acetyltransferase in Alzheimer’s disease, treatments based on the cholinergic hypothesis have been unsuccessful (Kaufman 1990a). With the goal of increasing the central nervous system concentrations of ACh, precursors of ACh including choline and lecithin have been tried, as well as centrally acting anticholinesterases such as physostigmine and tetrahydroaminoacridine, with the hope of decreasing ACh metabolism (Kaufman 1990b). ACh agonists such as arecoline, oxotremorine, and bethanechol have been investigated and release of ACh has been stimulated from cerebral neurons by using piracetam (a cyclic relative of GABA) and nafonyl oxalate (Praxilene) (Kaufman 1990b). These pharmacological interventions have yielded inconsistent results and been largely ineffective.

Because vasopressin levels are slightly decreased in the hippocampus of patients with Alzheimer’s disease and somatostatin is adversely affected as well, attempts were made to replace these agents with little effect. In the belief that improving blood flow might be of benefit, such agents as the metabolic enhancer and vasodilator ergoloid mesylates (Hydergine—an ergot alkaloid) were tried. Hydergine did seem to have some benefit; however, these effects may have been related to its mild antidepressant action (Jenike et al. 1986, Kaufman 1990b). Onset of action of any beneficial effects of Hydergine was quite long.

Corticotropin release is promoted by corticotropin-releasing factor, which is decreased in patients with AD, but effects of Hydergine was quite long. Thal 1994). Other unsuccessful drug trials included the use of the monoamine oxidase B inhibitor l-deprenyl, thiamine, oxalate (Praxilene) (Kaufman 1990b). These pharmacological interventions have yielded inconsistent results and been largely ineffective.

Whereas much attention has been focused on research aimed at understanding and altering the pathogenesis of AD, less work has been done regarding appropriate pharmacotherapy of the varied psychological manifestations of the disease. Depression is often associated with AD. If antidepressant medication is to be used, low doses (about one-third to one-half of the usual initial dose) are advised, and only agents with minimal anticholinergic activity should be employed. Appropriate choices would be the selective serotonin reuptake inhibitors such as paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft). Even these agents have the potential to increase confusion in Alzheimer’s patients. Agents such as Trazodone (Desyrel) and Mirtazapine (Remeron) have occasionally been employed because of their sedating properties. If tricyclic antidepressants are used, the secondary amines (desipramine, nortriptyline) are recommended over the tertiary ones (amitriptyline, doxepin). Careful attention to the possible side effects of these agents, particularly orthostatic hypotension, lowering of the seizure threshold, excessive fatigue, urinary retention, constipation, confusion, and accelerated memory impairment, is suggested. Most clinicians now feel that tricyclic antidepressants are inappropriate for this patient population.

Anxiety and psychosis, particularly paranoid delusions, are common in AD. Benzodiazepines can be disinhibiting in such patients and may exacerbate confusion. They should be avoided if possible. If minor tranquilizers are required, agents with a shorter duration of action (e.g., lorazepam, oxazepam) are preferred. Antipsychotic medications with high anticholinergic potential (thioridazine, chlorpromazine) may also affect memory adversely. While these agents have been favored in the past because of their tendency to produce sedation, newer agents such as olanzapine (zyprexa), risperdone (risperdal), and Quetiapine (Seroquel) have been reported to have lower incidences of neuroleptic-related side effects (Lerner et al. 2000, Teste et al. 2000, Torres et al. 2001). Haloperidol has less anticholinergic activity but has a greater tendency toward extrapyramidal effects. Some studies have associated the use of atypical antipsychotics to treat agitation and aggressiveness in Alzheimer’s patients with a higher incidence of sudden deaths in rare cases (Schneider et al. 2005).
Therefore, these agents should be reserved in most cases for those patients with both agitation and psychosis. If they are used, cardiac parameters such as QTc interval length should be monitored, and the lowest possible effective dose should be employed (Friedman 2006). In such patients, where agitation (and not psychosis) is a major factor, the use of low dose Valproic acid has been helpful (Hanson and Galvez-Jimenez 2004). These agents will be discussed in more detail in the consideration of management of delirious states. In summary, the psychopharmacological management of AD is designed to ameliorate cognitive deficits if possible; control agitated, psychotic, and dangerous behavior, and treat any underlying psychiatric disorder (e.g., major depression) that might be comorbid with dementia.

The appropriate management of AD entails more than psychopharmacological intervention. Other elements of the treatment plan should be environmental manipulation and support for the family.

In the attempt to maintain patients with Alzheimer's disease in their homes for as long as possible, some adjustments of their environment are important. Written daily reminders can be helpful in the performance of daily activities. Prominent clocks, calendars, and windows are important, and an effort should be made to minimize changes in the patient's daily activities. Repeated demonstrations of how to lock doors and windows and operate appliances are helpful, and arranging for rapid dialing of essential telephone numbers can be important. Maintaining adequate hydration, nutrition, exercise, and cleanliness is essential.

The family of the patient with Alzheimer's disease is also a victim of the disease. Family members must watch the gradual deterioration of the patient and accept that a significant part of their own lives must be devoted to the care of the disease. Difficult decisions about institutionalization are a victim of the disease. Family members must watch the gradual deterioration of the patient and accept that a significant part of their own lives must be devoted to the care of their daily activities. Repeated demonstrations of how to lock doors and windows and operate appliances are helpful, and arranging for rapid dialing of essential telephone numbers can be important. Maintaining adequate hydration, nutrition, exercise, and cleanliness is essential.

The family of the patient with Alzheimer's disease is also a victim of the disease. Family members must watch the gradual deterioration of the patient and accept that a significant part of their own lives must be devoted to the care of the individual. Difficult decisions about institutionalization and termination of life support are distinct possibilities, and the patients often turn their anger and paranoia toward the caregiver. Education is a valuable treatment tool for families. Information about the disease and peer support is available through Alzheimer's associations, and many such agencies provide family members with a companion for the patient to allow the family some time away. Many studies suggest that the primary reason for institutionalization of these patients is the tremendous burden of care they pose for their families. Aimless wandering seems to be a particularly disturbing behavior. Unfortunately, the unfamiliar surroundings of a nursing home often increase the patient's level of confusion and anxiety.

For these reasons, family members are at risk for depression, anxiety syndromes, insomnia, and a variety of other psychological manifestations. Should these occur, they should be promptly treated. The National Alzheimer's Education and Referral Service can be accessed by calling 1-800-621-0379.

Dementia due to Pick's Disease

Pick's disease is a rare form of progressive dementia clinically indistinguishable from Alzheimer's disease. It is about one-fifth as common as AD (Nolan et al. 1991). Pick's disease occurs in middle adult life and has a duration that varies from 2 to 15 years. It has a strong familial tendency, but definite genetic pattern has not been established (Kaufman 1990b). ACh levels are reduced.

The pathological features of Pick's disease involve prominent changes (e.g., sclerosis, atrophy) in the frontal and temporal lobes (Figure 51–8). The parietal and occipital lobes are spared. Alzheimer himself noted the argyrophilic (staining silver) intraneuronal inclusion of Pick's bodies.

The clinical features of Pick's disease are quite similar to those of Alzheimer's disease, and since neither condition is curable, an elaborate differential diagnosis is unnecessary. Because of parietal sparing, such features as apraxia and agnosia are less in common in Pick's disease, and visual–spatial ability, often impaired in Alzheimer's disease, is preserved (Kaufman 1990b). Given the prominent changes in the frontal lobe, disinhibited behavior, loss of social constraints, and lack of concern about appearance and matters of personal hygiene occur relatively early in Pick's disease. Such speech disorders as echolalia and logorrhea are common, and patients with Pick's disease are more likely to develop Klüver–Bucy syndrome (orality, hyperphagia, hypersexual- ity, placidity) indicative of damage to the temporal lobes (Torres et al. 2001). Significant memory impairment may occur relatively late in the course, and eventually the patient becomes listless, mute, and ultimately decerebrate and comatose. The treatment of Pick's disease is symptomatic.

Dementia due to Parkinson's Disease

James Parkinson did not consider cognitive deficits to be a feature of the disease that now bears his name (Berg et al. 1994). In fact, although dementia rarely occurs as an initial symptom of Parkinson's disease, it is found in nearly 40% of such patients older than 70 years of age (Kaplan et al. 1994). Approximately one million people in the United States have the disease with 50,000 new cases being diagnosed each year.

The prevalence for persons over 60 is 1%. The disease results from loss of dopamine production in the basal ganglia, and can be idiopathic or postencephalitic. Usually the patient is 50 years of age or older, and unlike Alzheimer's and Pick's dementias, this disease occurs slightly more often in men (Berg et al. 1994). Dementia most commonly occurs in cases of Parkinson's disease in which the decline has been rapid and response to anticholinergics has been poor.
The pathology of Parkinson’s disease involves depigmentation of the so-called pigmented nuclei of the brain (locus caeruleus, substantia nigra). These nuclei then contain eosinophilic Lewy bodies. As in Alzheimer’s disease the cerebral cortex of many of these patients contains many senile plaques and neurofibrillary tangles, loss of neurons, and decreased concentrations of choline acetyltransferase (Kaufman 1990c). Patients with Parkinsonian dementia also have reduced choline acetyl transferase (CAT) in the cerebral cortex and substantia nigra (Kaufman 1990c).

The clinical features of Parkinson’s disease are well described, with the cardinal triad being tremor, rigidity, and bradykinesia. Associated features include postural instability, a festinating gait, micrographia, seborrhea, urinary changes, constipation, hypophonia, and an expressionless facial countenance. The tremor in Parkinson’s disease has a regular rate and is most prominent when the patient is sitting with arms supported; it has therefore been described as “intention tremors.” Paranoid delusions and visual hallucinations may occur, but auditory hallucinations are rare. Antipsychotics with low incidence of extrapyramidal symptoms such as quetiapine are recommended.

The pharmacological treatment of Parkinson’s disease involves the use of a number of categories of medication. These include Selegiline (Eldepryl, Somerset) a selective monoamine oxidase inhibitor, Levodopa, other dopamine agonists (Pramipexole [Mirapex], Bromocriptine, Pergolide mesylate [Permax, Elan], Amantidine), and various anticholinergic agents (benztropine). Selegiline should not be given to patients on antidepressant medication, and there is a risk that dopaminergic agents may produce/activate psychosis or mania and anticholinergic drugs may increase confusion. When discontinuing levodopa after a long course of treatment, the drug should be tapered so as to prevent a discontinuation syndrome similar in nature to the neuroleptic malignant syndrome. Some medications (Metoclopramide, Droperidol, several antipsychotics) may produce Parkinsonian features such as masked facies, sparsity of speech, and tremor) and in those cases the appropriate course of treatment is to discontinue the offending medication (Mamo et al. 2002). Several researchers are looking into the possibility of using embryonic stem cells implants as treatment for Parkinson’s disease and several other conditions.

Deep brain stimulation (DBS) is a surgical procedure used to treat Parkinson’s disease in those patients whose symptoms cannot be adequately controlled with medication. DBS uses a surgically implanted, battery operated medical device called a neurostimulator to deliver electrical stimulation to targeted areas of the brain that control movement, blocking the abnormal nerve signals that cause tremor and other Parkinson’s disease symptoms. The usual targets of stimulation are the thalamus, subthalamus nucleus, and the globus pallidus. The tip of the electrode is positioned within the targeted brain area and an extension wire is passed under the skin. The third component, the neurostimulator, is implanted lower in the chest or under the skin over the abdomen. Ideally, electrical impulses are sent from the neurostimulator up along the extension wire and into the brain where they interfere with and block the electrical signals that cause Parkinson’s disease symptoms.

Dementia due to Huntington’s Disease

Dementia is also a characteristic of Huntington’s disease, an autosomal dominant inheritable condition localized to chromosome 4. Unfortunately, this condition does not become apparent until age 35–45 years, usually after childbearing has occurred. Fifty percent of offspring are affected. There is also a juvenile form of the disease. Huntington’s disease affects about 4 in 100,000 people, making it a significant cause of dementia in middle-aged adults (Teste et al. 2000). The pathology of Huntington’s disease involves selective destruction in the caudate and putamen (Teste et al. 2000). In the caudate nuclei, GABA concentrations are reduced to 50% of normal (Teste et al. 2000). The frontal lobes of the cerebral cortex are also involved, but GABA and choline acetyltransferase concentrations are normal.

The most noticeable clinical feature of Huntington’s disease is the movement disorder, which involves both choreiform movements (frequent movements that cause a jerking motion of the body) and athetosis (slow writhing movements). In the juvenile form of Huntington’s disease, which represents about 3% of all cases, the chorea is replaced by dystonia, akinesia, and rigidity, and the course of the disease is more rapid than in the adult form (Teste et al. 2000). In the early stages of the disease, the chorea is not as noticeable and may be disguised by the patient by making the movements seem purposeful.

The dementia typically begins between 1 year before or 1 year after the chorea and, unlike patients with other dementias, patients with Huntington’s disease are often well aware of their deteriorating mentation. This may be a factor in the high rates of suicide and alcoholism associated with this condition. Although attempts have been made to increase ACh and GABA concentrations in these patients, such pharmacological interventions have been unsuccessful, and the dementia is untreatable. Genetic counseling is indicated.

Vascular Dementia

Vascular dementia usually results from multiple CVAs or one significant CVA. It is generally considered the second most common cause of dementia after Alzheimer’s disease, accounting for about 10% of all cases (Kaufman 1990b, Korvath et al. 1989). Men are twice as likely as women to be diagnosed with this vascular dementia (Torres et al. 2001). Vascular dementia is characterized by a stepwise progression of cognitive deterioration with accompanying lateralizing signs. It is always associated with evidence of systemic hypertension and usually involves renal and cardiac abnormalities. Risk factors for the development of a vascular dementia include those generally associated with obstructive coronary artery disease, including obesity, hypercholesterolemia, smoking, hypertension, stress, and lack of exercise. The actual incidence of vascular dementia has decreased somewhat with better standards of care, improved diagnostic techniques, and lifestyle changes.

Vascular dementia and Alzheimer’s are sometimes difficult to distinguish because of overlaps in symptoms, pathology, and comorbidity patterns. In addition, many patients have concomitant Alzheimer’s and Vascular dementia (“mixed dementia”). In one study, concomitant Alzheimer’s disease was present in 77% of Vascular
Vascular Dementia

A. The development of multiple cognitive deficits manifested by both
   (1) memory impairment (impaired ability to learn new information or to recall previously learned information)
   (2) one (or more) of the following cognitive disturbances:
      (a) aphasias (language disturbances)
      (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
      (c) agnosias (failure to recognize or identify objects despite intact sensory function)
      (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)

B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.

C. Focal neurological signs and symptoms (e.g., exaggeration of deep tendon reflexes, extensor plantar response, pseudobulbar palsy, gait abnormalities, weakness of an extremity) or laboratory evidence indicative of cerebrovascular disease (e.g., multiple infarctions involving cortex and underlying white matter) that are judged to be etiologically related to the disturbance.

D. The deficits do not occur exclusively during the course of a delirium.

Code based on predominant features:

290.41 With delirium: if delirium is superimposed on the dementia
290.42 With delusions: if delusions are the predominant feature
390.41 With depressed mood: if depressed mood (including presentations that meet full symptom criteria for a major depressive episode) is the predominant feature. A separate diagnosis of mood disorder due to a general medical condition is not given.
209.40 Uncomplicated: if none of the above predominates in the current clinical presentation

Specify if:

With behavioral disturbance

Coding note: Also code cerebrovascular condition on Axis III.

Dementia patients. In addition, vascular factors contribute to the development of dementia in patients with Alzheimer’s and Alzheimer’s and Vascular dementia share several risk factors and have shared pathology (e.g., lacunae, white matter lesions). The presence of mixed Vascular dementia and Alzheimer’s disease in combination has been underestimated in the older population.

Clinical Features

Vascular dementia is characterized by the early appearance of lateralizing signs. Spasticity, hemiparesis, ataxia, and pseudobulbar palsy are common. Pseudobulbar palsy is associated with injury to the frontal lobes and results in impairment of the corticobulbar tracts. It is characterized by extreme emotional lability, abnormal speech cadence, dysphagia, hyperactive jaw jerk, deep tendon reflexes, and Babinski’s reflex.

CT, MRI, and gross specimens show cerebral atrophy and infarctions, with the radiological procedures showing multiple lucencies and the gross specimens revealing distinct white matter lesions (Hershey et al. 1987, Kaufman 1990b) (Figures 51–9 to 51–11). The EEG is abnormal but nonspecific, and positron emission tomography reveals hypometabolic areas (Kaufman 1990b).

Vascular dementia is differentiated from AD on the basis of its mode of progression, early appearance of neurological signs, and radiographical evidence of cerebral ischemia.

Treatment

Primary prevention and secondary prevention are important in the treatment of cerebrovascular disorders. Lifestyle changes are effective in arresting the progress of the disease; however, no known pharmacological treatment can reverse the effects of a completed stroke (Korvath et al. 1989).
Infectious Causes of Dementia

Subacute Sclerosing Panencephalitis
Subacute sclerosing panencephalitis is an infectious cause of dementia that usually appears in childhood. The average age at onset is 10 years, and most patients are male and live in rural areas (Kaufman 1990b, Ziber et al. 1983). It is diagnosed on the basis of periodic complexes on the EEG and an elevated measles titer in the cerebrospinal fluid (CSF). The CT scan shows cerebral atrophy and dilated ventricles. Myoclonus and dementia are prominent features.

It has been postulated that a mutant measles virus is the infectious agent, based on the high CSF measles antibody titer and the fact that the disease is virtually nonexistent in children who have been vaccinated for measles (Kaplan et al. 1994). Affected patients show an insidious onset of impairment of cognition usually preceded by behavioral problems.

Creutzfeldt-Jakob Disease
Dating from original descriptions by Creutzfeldt in 1920 and Jakob in 1921, this disease has received intense scientific scrutiny (Karp 1984). The primary features of Creutzfeldt-Jakob disease are dementia, basal ganglia and cerebellar dysfunction, myoclonus, upper motor neuron lesions, and rapid progression to stupor, coma, and death in a matter of months. The disease generally affects people 65 years of age or older, with a life expectancy of 1 month to 6 years after onset and an average life span of 15 months. The clinical and pathological features of Creutzfeldt-Jakob have been produced experimentally by injecting animals with brain tissue from affected adults. It has unknowingly been transferred to humans by organ transplantation, cerebral electrodes, and pituitary growth hormone (Marzewski et al. 1988, Rappaport and Graham 1987). These incidents, although tragic, illustrated the infectious nature of this condition, and the agent of transmission is believed to be a prion-containing protein (not DNA or RNA). These prions have been detected in the cerebral cortex of autopsy specimens of both patients with Creutzfeldt-Jakob disease and victims of kuru, a fatal disease transmitted by cannibalism (Kaplan et al. 1994, Prusiner 1987). Slow viruses have also been implicated as infectious agents in kuru. Creutzfeldt-Jakob has been transmitted to humans who consumed animals contaminated with the disease (so-called Mad Cow Disease).

The memory loss in Creutzfeldt-Jakob disease involves all phases of memory, with recent (secondary) memory the most impaired. Personality changes, immature behavior, and paranoia are early signs, and virtually every aspect of brain functioning can be involved. Motor disorders including rigidity, incoordination, paresis, and ataxia usually follow.

As with subacute sclerosing panencephalitis, the EEG in Creutzfeldt-Jakob disease shows periodic complexes and biopsy specimens reveal a characteristic spongiform encephalopathy and occasional amyloid plaques (Kaufman 1990b) (Figure 51–12).

Acquired Immunodeficiency Syndrome
AIDS was first described in the United States in 1979. Two years later, the Center for Disease Control and Prevention announced the unexplained occurrence of Pneumocystis carinii pneumonia and Kaposi’s sarcoma in previously
healthy homosexual men (Wilson et al. 1991). Since then the number of AIDS cases has risen exponentially. The CDC reports that as of December 31, 2005, 988,376 individuals had been diagnosed with AIDS in the United States. Nine thousand children under age 13 have been diagnosed. Deaths from AIDS-related illnesses have reached 550,394 in the United States alone. Worldwide, about 40 million people, including 3 million children have AIDS. Forty-eight percent of the worldwide cases are women, and 95% of AIDS cases are in undeveloped countries. The number of people infected is postulated to be as much as 50–100 times the number of people diagnosed with AIDS and 80–90% of people infected have not been tested.

In the developed countries, the death rate from AIDS has been on the decline since the advent of new medication regimens utilizing traditional antiretrovirals and the newer protease inhibitors. These medication cocktails have also decreased the incidence of AIDS Dementia Complex, so that physicians are now more likely to see AIDS-related Delirium secondary to infection, metabolic disarray, and medication rather than traditional AIDS dementia.

In the truest sense, AIDS is not a disease but an increased susceptibility to a variety of diseases caused by loss of immunocompetence. It may result from infection with HIV, a retrovirus that attaches to the CD4 molecule on the surface of the T4 (thymus-derived) lymphocyte. Then, using reverse transcriptase, the virus reverses the usual sequence of genetic information and becomes integrated into the host cell's DNA (Kaufman 1990b). The ultimate result is destruction of the T4 cell, replication of the virus, a defect in cell-mediated immunity, and the development of various opportunistic infections and neoplasms.

The epidemiology of HIV spectrum disease has changed significantly in the 16 years since its identification. Initially, homosexual and bisexual men with multiple partners were, according to the Center for Disease Control and Prevention, the highest risk group. Intravenous drug abusers and recipients of tainted blood products were soon added to high-risk groups. In the 1990s the number of new infections among homosexual men decreased significantly and rates for women, intravenous drug abusers who shared contaminated needles, and infants born to infected mothers increased significantly. Intravenous drug abusers, regardless of sexual orientation, represent the fastest growing population of the newly infected people. Conversely, instances of transmission by blood products have decreased since the development of laboratory testing for HIV antibodies. The Center for Disease Control and Prevention has now established a reactive HIV antibody screen, presence of an opportunistic condition, and a CD4+ cell count of 200 or less (normal being 1000–1500) as criteria for the diagnosis of AIDS.

AIDS is now best considered as part of the spectrum of HIV infection (Wilson et al. 1991). There are four stages of infection.

Stage 1: Acute Infection: Most infected persons remember no signs or symptoms at the time of the initial infection. The acute syndrome follows infection by 4–6 weeks and is characterized by fevers, rigors, muscle aches, maculopapular rash, diarrhea, and abdominal cramps. These symptoms, often mistaken for those of influenza, resolve spontaneously after 2–3 weeks.

Stage 2: Asymptomatic carrier: This stage follows the acute infection. The patient is without symptoms for a variable amount of time. The mean symptom-free period has increased significantly since the disease was first identified and is now about 10 years. Most of the estimated 2 million infected Americans are at this stage. Even though these individuals are asymptomatic, they are carriers of the disease and can infect others.

Stage 3: Generalized adenopathy: In older terminology, this stage was referred to as the AIDS-related complex. It is characterized by palpable lymph nodes that persist for longer than 3 months. These nodes must be outside the inguinal area and due to no other condition except HIV.

Stage 4: Other diseases:

1. Constitutional symptoms such as lingering fever, wasting syndromes, and intractable diarrhea.
2. Secondary infections including P. carinii pneumonia, cytomegalovirus retinitis, parasitic colitis, and oral esophageal thrush.
3. Secondary neoplasms such as Kaposi’s sarcoma and B-cell lymphomas.
4. Neurological diseases (AIDS dementia complex).

Thus, the diagnosis of AIDS is made when an infected individual develops either a CD4+ cell count of less than 200 or a certain condition listed in stage 4 (Wilson et al. 1991).

Dementia due to HIV Diseases

Initially, the behavioral abnormalities observed in HIV-positive patients were attributed to the emotional reaction to the disease. Subsequent investigations demonstrated that neurological complications occur in 40–45% of patients with AIDS, and in about 10% of cases neurological signs are the first feature of the disease (Berg et al. 1994, Pajeau and Roman 1992). The neurological signs present in AIDS are believed to be related to both the direct effects of the virus on cells (such as macrophages) that enter the central nervous system and the neurological conditions that opportunistically affect these patients. Ho et al. 1987 reported...
that 90% of the brains of AIDS patients examined showed neuropathological abnormalities. AIDS dementia must be considered in the differential diagnosis of dementia in older patients, because about 10% of AIDS patients are older than 50 years of age (Berg et al. 1994, Scharnhorst 1992).

Patients with AIDS dementia present with impairments of cognitive, behavioral, and motor systems. The cognitive disorders include memory impairment, confusion, and poor concentration. Behavioral features include apathy, reclusivity, anhedonia, depression, delusions, and hallucinations. Motor symptoms include incoordination, lower extremity paresis, unsteadiness, and difficulty with fine motor movements like handwriting and buttoning clothes (Berg et al. 1994, Kaufman 1990b, Scharko et al. 2006). As the disease progresses, parkinsonism and myoclonus develop.

Localizing signs such as tremors, focal seizures, abnormal reflexes, and hemiparesis can result. The protozoan Toxoplasma gondii commonly infects the central nervous system and can be diagnosed by CT or by increased toxoplasmosis antibody titers (Kaufman 1990b). Discrete cerebral lesions are also produced by fungi such as Candida and Aspergillus, Mycobacterium tuberculosis, and viruses such as cytomegalovirus and papovavirus. Papovavirus causes progressive multifocal leukoencephalopathy (Kaufman 1990b). Tertiary syphilis has increased significantly since the advent of AIDS, and neoplasms such as lymphomas, metastatic Kaposi’s sarcoma, and gliomas are also causes of AIDS dementia.

Many confounding factors can increase cognitive dysfunction in AIDS, including a high incidence of drug and alcohol abuse; medications such as histamine H 2 receptor antagonists (cimetidine), corticosteroids, narcotics, and antiviral drugs (e.g., zidovudine (formerly azidothymidine, AZT)) that increase confusion; and coexistent depression (Table 51–5).

The CT scan shows cerebral atrophy and MRI reveals nonspecific white matter abnormalities (Kaufman 1990b). Neoplasms and lesion such as toxoplasmosis are also visible. Lumbar puncture reveals a pleocytosis and elevated protein levels, and autopsy demonstrates an atrophic brain with demyelination, multinuclear giant cells, and gliosis of the cerebral cortex (Kaufman 1990b).

### Treatment

The increase in life span of patients affected by HIV is directly related to improvements in treating the opportunistic conditions that occur. Aerosol pentamidine as prophylaxis for P. carinii pneumonia and ganciclovir for cytomegalovirus retinitis are examples of effective intervention. The use of antiviral agents has generated some controversy. Zidovudine, the first antiviral treatment for AIDS approved by the US Food and Drug Administration, increased or stabilized CD4+ cell concentrations in early studies. Later investigations revealed that zidovudine has a narrow window of effectiveness and may not be appropriate immediately after such exposure as a needle stick. Side effects of zidovudine include blood dyscrasias, peripheral neuropathy, seizures, lymphomas, confusion, anxiety, mania, and a Vernicke-Korsakoff type of picture (Kaufman 1990b).

Studies suggest that administration of zidovudine to HIV-positive patients during pregnancy, intravenously during delivery, and to the neonate for 6 weeks after birth can decrease the percentage of infants who seroconvert from 30% to as low as 10%. However, results of studies of the effectiveness of zidovudine in children already HIV-positive have been disappointing.

Subsequent antiviral agents such as dideoxynosine and dideoxycytidine (DDC) have been associated with painful neuropathy and pancreatic disorders. DDC in particular can produce serious neuropsychiatric complications. Combined therapy with two antiviral agents may be more effective than single-drug therapy. May pharmaceutical companies are combining two antivirals into a single pill, and the development of protease inhibitor agents such as indinavir (Crixivan) and nelfinavir (Viracept) have been especially effective in retarding the progression of the disease.

The treatment of neuropsychiatric disorders in AIDS involves utilizing agents that are least likely to interfere with other medications prescribed, or to exacerbate the symptoms of the disease. AIDS-related depression has responded well to the selective serotonin reuptake inhibitors (SSRIs) and to psychostimulants. Some HIV drugs can have interactions with SSRIs, particularly ritonavir (Norvir) and the
SSRIs themselves, especially paroxetine and fluoxetine can interact with other agents the HIV patient may have been prescribed, such as antiarrhythmics, benzodiazepines, and anticonvulsants by inhibiting the cytochrome P-450 enzyme system. Careful attention to drug–drug interactions, using lower starting doses of certain psychiatric drugs, and monitoring of blood levels of affected medications are recommended. Among the psychostimulants, methylphenidate is preferred to dextroamphetamine, because of the latter’s tendency to produce dyskinesias. Use of stimulants for treating in patients with a history of substance abuse is not recommended. Anticholinergic agents have a number of side effects such as mydriasis, decreased gastrointestinal motility, postural hypotension; however, low dose tricyclic antidepressants are often used for their sedative, analgesic, and appetite stimulant properties. Most antidepressants and some mood stabilizers and antipsychotics can cause bone marrow suppression so they should be used with care, and hematologic parameters routinely monitored. Lithium carbonate, which produces a leukocytosis, may be of benefit in recurrent unipolar and treatment-resistant depression, but may potentiate AIDS-related diarrhea. Many of the drugs used to treat AIDS-related conditions may produce untoward psychiatric effects. Depression has been well documented as a side effect of indinavir (Crixivan), and nelfinavir (Viread) has been associated with anxiety, depression, mood lability, and even suicidality. St. John’s Wort may decrease the concentration of many of the protease inhibitors and is therefore contraindicated in patients taking these agents.

In summary, AIDS dementia is best treated by identifying the associated medical condition, instituting appropriate therapy, and managing behavior in the interim.

Neurosphylis
During the late 19th century, neurosyphilis was responsible for a significant number of admissions to psychiatric hospitals (Kaufman 1990b). The condition had decreased in incidence after the causative agent (Treponema pallidum) was identified and penicillin treatment became readily available. The rise of AIDS in the 1980s and 1990s has led to an increase in the number of diagnosed cases of neurosyphilis (Kaufman 1990b). Infection with T. pallidum is generally divided into four stages (Summergrad et al. 1993).

Primary syphilis occurs 3–6 weeks after contact with the organism. The symptoms include a chancre at the site and regional lymphadenopathy. Affected persons are infectious.

Secondary syphilis begins 6–8 weeks after the primary stage. It is manifested by a maculopapular rash over the trunk, and especially over the soles of the feet and palms. The person is constitutionally ill with fever and adenopathy. Occasionally, secondary syphilis is asymptomatic in the last few weeks.

Latent syphilis presents with a normal examination and seropositivity. If patients with latent syphilis continue to have a normal CSF profile 2 years after diagnosis, they are at low risk for neurosyphilis.

Late syphilis consists of ongoing inflammatory disease most likely in the aorta or nervous system (neurosyphilis), the latter occurring in about 10% of patients. The neurosyphilis of the late stage can consist of (1) asymptomatic neurosyphilis, (2) meningeovascular syphilis, and (3) parenchymal neurosyphilis. The parenchymal neurosyphilis consists of general paresis, which occurs about 20 years after infection and includes cognitive impairment, myoclonus, dysarthria, personality changes, irritability, psychosis, grandiosity, and mania (Summergrad et al. 1993, Ross et al. 1990). Untreated general paresis leaves the patient a helpless invalid. The second form of parenchymal neurosyphilis is tabes dorsalis with onset 25–30 years after initial infection. Tabes features loss of position and vibratory sense, areflexia in lower extremities, chronic pain, ataxia, and incontinence (Summergrad et al. 1993).

The original screening test for syphilis is the Venereal Disease Research Laboratory (VDRL) test or the Rapid Plasma Reagin (RPR) test. These tests have a significant false-positive rate, especially in the elderly and in patients with addictions and autoimmune disorders (Kaufman 1990b). The VDRL test may revert to negative after a number of years, and 20–30% of patients in the stage of late syphilis have a negative (nonreactive) VDRL result. A more specific test is the fluorescent treponemal antibody screen, which is positive 95% of the time in neurosyphilis. The false-positive rate for the fluorescent treponemal antibody screen is extremely low, and reversion to a nonreactive estate is unlikely. In addition to a positive VDRL result, the CSF in patients with neurosyphilis generally shows pleocytosis.

Dementia secondary to neurosyphilis produces various physical findings in advanced cases. These may include dysarthria, Babinski’s reflex, tremor, Argyll Robertson pupils, myelitis, and optic atrophy. Although notorious, delusions of grandeur in neurosyphilis are rare. A reactive CSF VDRL result or a positive serum fluorescent treponemal antibody result in a patient with neurological symptoms who cannot document treatment should be treated with appropriate therapy. Penicillin often improves cognitive deficits and corrects CSF abnormalities, but complete recovery is rare.

Dementia due to Head Trauma
Head trauma is the leading cause of brain injury for children and young adults (Berg et al. 1994). It is estimated that more than 7 million head injuries and 500,000 related hospital admissions occur in the United States annually (Berg et al. 1994, Bond 1986). Traumatic head injuries result in concussions, contusions, or open head injuries, and the physical examination often reveals such features as blood behind the tympanic membranes (Battle’s sign), infraorbital ecchymosis, and pupillary abnormalities (Berg et al. 1994). The psychiatric manifestations of an acute brain injury are generally classified as a delirium or amnestic disorder; however, head trauma-induced delirious states often merge into a chronic dementia. Episodes of repeated head trauma, as in dementia pugilistica (punchdrunk syndrome), can lead to permanent changes in cognition and thus are appropriately classified as demented states. The punchdrunk syndrome is seen in aging boxers and includes dysarthric speech, emotional lability, slowed thought, and impulsivity (Berg et al. 1994, Jordan 1987, Kaufman 1990b, Mawdsley and Ferguson 1953).

A single head injury may result in a postconcussional syndrome with resultant memory impairment, alterations in mood and personality, hyperacusis, headaches, easy fatigueability, anxiety, belligerent behavior, and dizziness. Alcohol abuse, postural hypotension, and gait disturbances are often associated with head injuries that result in dementia.
 Substance-Induced Persisting Dementia

In instances in which the features of dementia result from central nervous system effects of a medication, toxin, or drug of abuse (including alcohol), the diagnosis of dementia due to the persisting effects of a substance should be made (First 1994). The most common dementias in this category are those associated with alcohol abuse, accounting for about 10% of all dementias (Korvath et al. 1989). The diagnosis of alcohol abuse dementia requires that the cognitive changes persist after the cessation of alcohol use and are not the result of changes in mentation associated with early abstinence, amnestic episodes (blackouts), or Wernicke-Korsakoff syndrome. In addition to various nutritional deficiencies and the toxic effects of alcohol itself, alcohol abusers are more prone to develop dementia as a result of head trauma and chronic hepatic encephalopathy.

Epidemiology of Alcohol-Induced Dementia

Chronic alcohol abuse is the third leading cause of dementia. It affects a higher proportion of women than men, and alcohol-induced dementia is a relatively late occurrence, generally following 15–20 years of heavy drinking (Korvath et al. 1989). Dementia is more common in individuals with alcoholism who are malnourished. The CT scan shows cortical atrophy and ventricular dilatation after about 10 years with neuronal loss, pigmentary degeneration, and glial proliferation (Korvath et al. 1989). The frontal lobes are the most affected, followed by parietal and temporal areas (Korvath et al. 1989). The amount of deterioration is related to age, number of episodes of heavy drinking, and total amount of alcohol consumed over time.

Clinical Features

Alcohol-induced dementia secondary to the toxic effects of alcohol develops insidiously and often presents initially with changes in personality. Increasing memory loss, worsening cognitive processing, and concrete thinking follow. The dementia may be affected by periodic superimposed delirious states including those caused by recurrent use of alcohol and cross-sensitive drugs, respiratory disease related to smoking, central nervous system hemorrhage secondary to trauma, chronic hypoxia related to recurrent seizure activity, folic acid deficiency, and higher rates of some neoplasms among those with alcoholism (Table 51–6).

Treatment

The presence of dementia makes the treatment of alcoholism more difficult. Most treatment programs depend on education about substance abuse, working the 12 steps, some degree of sociability, and such relatively abstract concepts as secondary gratification and a higher power. Such treatment programs are often reluctant to engage in the painstaking repetition that patients with alcohol-induced dementia often require. These patients may become frustrated in peer support groups such as Alcoholics Anonymous. Despite these obstacles, patients with alcoholism who complete a treatment program and remain sober do have some improvement in their mental state. There is an initial improvement that peaks at 3–4 weeks, followed by a slow but steady improvement detected at 6–8 months. In general, the presence of a cognitive

neural effects of selected inhalants, including alcohol and tobacco use, may produce neurological changes. Abuse of organic solvents (inhalants) has been associated with neurological changes. Inhalants are generally classified as anesthetics (halothane, chloroform, ether, nitrous oxide), solvents (gasoline, paint thinner, antifreeze, kerosene, carbon tetrachloride, aerosols, insecticides, deodorants, hair sprays), and nitrites (amyl nitrite). The solvent category is particularly toxic to the brain. In addition, acute anoxia may result from the common practice of inhaling a substance with a plastic bag around the head. Such neurological findings as peripheral neuropathy, paresis, paresthesias, areflexia, seizures, signs of cerebellar damage, and Babinski's sign are common. Although the cerebellum is often involved, any area of the cerebral cortex may be affected.

**Other Medical Conditions**

**Other Substances**

Many other agents can produce dementia as a result of their persisting effects. Exposure to such heavy metals as mercury and bismuth, chronic contact with various insecticides and use of various classes of drugs of abuse may produce dementia. In particular, the abuse of organic solvents (inhalants) has been associated with neurological changes. Normal-pressure hydrocephalus is generally considered the fifth leading cause of dementia after Alzheimer's, vascular, alcohol-related, and AIDS dementias. Long considered irreversible but often merely arrestable, normal-pressure hydrocephalus is a syndrome consisting of dementia, urinary incontinence, and gait apraxia. Normal-pressure hydrocephalus is generally considered the fifth leading cause of dementia after Alzheimer's, vascular, alcohol-related, and AIDS dementias.

### Dementia due to Other General Medical Conditions

**Normal-Pressure Hydrocephalus**

Normal-pressure hydrocephalus is generally considered the fifth leading cause of dementia after Alzheimer's, vascular, alcohol-related, and AIDS dementias. Long considered irreversible but often merely arrestable, normal-pressure hydrocephalus is a syndrome consisting of dementia, urinary incontinence, and gait apraxia. It results from subarachnoid hemorrhage, meningitis, or trauma that impedes CSF absorption.

Unlike other dementias, the dementia caused by normal-pressure hydrocephalus has physical effects that often overshadow the mental effects. Psycho-motor retardation, marked gait disturbances, and in severe cases, complete incontinence of urine occur. A cisternogram is often helpful in the diagnosis, and CT and MRI show ventricular dilatation without cerebral atrophy. CSF analysis reveals a normal opening pressure, and glucose and protein determinations are within the normal range.

The hydrocephalus can be relieved by insertion of a shunt into the lateral ventricle to drain CSF into the chest or abdominal cavity, where it is absorbed. Clinical improvement with shunting approaches 50% with a neurosurgical complication rate of 13–25%.

### Wilson's Disease

Hepatolenticular degeneration (Wilson's disease) is an inherited autosomal recessive condition associated with dementia, hepatic dysfunction, and a movement disorder. Wilson's disease should be considered along with Huntington's disease, AIDS dementia, substance abuse dementia, head trauma, and subacute sclerosing panencephalitis in the differential diagnosis of dementia that presents in adolescence and early adulthood.

### Other Medical Conditions

In addition to the conditions mentioned previously, other medical illnesses can be associated with dementia. These include endocrine disorders (hypothyroidism, hypoparathyroidism), chronic metabolic conditions (hypocalcemia, hypoglycemia), nutritional deficiencies (thiamine, niacin, vitamin B<sub>12</sub>), structural lesions (brain tumors, subdural hematomas), and multiple sclerosis.

### Dementia due to Multiple Etiologies

Dementia may have more than one cause in a particular patient. Certain types of dementia tend to occur together, including alcohol-induced persisting dementia and dementia caused by head trauma, vascular dementia, and dementia of the Alzheimer type, and alcohol abuse dementia.
all conditions contributing to the dementia should be diagnosed.

Treatment of Dementia

Most of the treatment strategies for dementia have been discussed previously (see treatment of dementia of the Alzheimer type). In summary, the management of dementia involves (1) identification and, if possible, correction of the underlying cause; (2) environmental manipulation to reorient the patient; (3) intervention with the family by means of education, peer support, providing access to community organizations, discussing powers of attorney, living wills, and institutionalization if appropriate, and arranging therapy if indicated; and (4) pharmacological management of psychiatric symptoms and behavior. For psychotic patients, low dose antipsychotics with minimal anticholinergic potential and occasionally short-acting benzodiazepines (e.g., lorazepam) are the drugs of choice. Because depression occasionally accompanies dementia, pharmacotherapy with antidepressants of low anticholinergic and hypotensive potential is often indicated. For patients with dementia secondary to drug or alcohol abuse, appropriate referral for rehabilitation is essential. Some elderly patients may be further disinhibited by benzodiazepines. Tables 51–8 to 51–10 summarize the causes of dementia.

Delirium

Delirium (acute confusional state, toxic metabolic encephalopathy) is the behavioral response to widespread disturbances in cerebral metabolism (Engel and Roman 1959, Lipowski 1983, 1987, 1989, 1990). The term delirium is derived from the Latin for “off the track,” and some have labeled the condition reversible madness (Lipowski 1983, 1989, Tobias et al. 1988). Like dementia, delirium is not a disease but a syndrome with many possible causes that result in a similar constellation of symptoms. DSM-IV-TR describes five categories of delirium based on etiology (Table 51–11).

Historical Perspective

Delirium was reported as early as Hippocrates’ time by Celsus in the first century AD (Korvath et al. 1989). In 1813, Sutton described the syndrome of delirium tremens and its relationship to alcoholism and Wernicke described the condition that bears his name (Korvath et al. 1989). Lipowski (1983, 1987, 1990) proposed a concept of delirium that would include a variety of behavioral syndromes,
some global, others focal, and others that would mimic the common functional disorders (Korvath et al. 1989).

**Epidemiology**
The overall prevalence of delirium in the community is low, but delirium is common in hospitalized patients. Lipowski (1987) reported studies of elderly patients and suggested that about 40% of them admitted to general medical wards showed signs of delirium at some point during the hospitalization. Because of the increasing numbers of elderly in this country and the influence of life-extending technology, the population of hospitalized elderly is rising; so is the prevalence of delirium. The intensive care unit, geriatric psychiatry ward, emergency department, alcohol

**DSM-IV-TR Criteria**

**Dementia due to Multiple Etiologies**

A. The development of multiple cognitive deficits manifested by both

(1) memory impairment (impaired ability to learn new information or to recall previously learned information)

(2) one (or more) of the following cognitive disturbances:

(a) aphasia (language disturbance)

(b) apraxia (impaired ability to carry out motor activities despite intact motor function)

(c) agnosia (failure to recognize or identify objects despite intact sensory function)

(d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)

B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.

C. There is evidence from the history, physical examination, or laboratory findings that the disturbance has more than one etiology (e.g., head trauma plus chronic alcohol use, dementia of the Alzheimer's type with the subsequent development of vascular dementia).

D. The deficits do not occur exclusively during the course of a delirium.

**Coding note:** Use multiple codes based on specific dementias and specific etiologies, e.g., 290.0 dementia of the Alzheimer's type, with late onset, uncomplicated; 290.40 vascular dementia, uncomplicated.

Pathophysiology

ACh is the primary neurotransmitter believed to be involved in delirium, and the primary neuroanatomical site involved is the reticular formation (Kovath et al. 1989). Thus, one of the frequent causes of delirium is the use of drugs with high anticholinergic potential. Patients with impaired cholinergic transmission, such as those with Alzheimer’s disease, are especially susceptible. As the principal site of regulation of arousal and attention, the reticular formation and its neuroanatomical connections play a major role in the symptoms of delirium. The major pathway involved in delirium is the dorsal tegmental pathway projecting from the mesencephalic reticular formation to the tectum and the thalamus (Kaplan et al. 1994).

Clinical Features

According to DSM-IV-TR, the primary feature of delirium is a diminished clarity of awareness of the environment (First 1994). Symptoms of delirium are characteristically global, of acute onset, fluctuating, and of relatively brief duration. In most cases of delirium, an often overlooked prodrome of altered sleep patterns, unexplained fatigue, fluctuating mood, sleep phobia, restless sleep, anxiety, and nightmares occurs. A review of nursing notes for the days before the recognized onset of delirium often illustrates early warning signs of the condition.

Several investigators have divided the clinical features of delirium into abnormalities of (1) arousal, (2) language and cognition, (3) perception, (4) orientation, (5) mood, (6) sleep and wakefulness, and (7) neurological functioning (Kaplan et al. 1994).

The state of arousal in delirious patients may be increased or decreased (Foreman and Milisen 2004). Some patients exhibit marked restlessness, heightened startle, hypervigilance, and increased alertness. This pattern is often seen in states of creased alertness. This pattern is often seen in states of withdrawal from depressive substances (e.g., alcohol) or intoxication by stimulants (phenacyclidine, amphetamine, lysergic acid diethylamide). Patients with increased arousal often have such concomitant autonomic signs as pallor, sweating, tachycardia, mydriasis, hyperthermia, piloerection, and gastrointestinal distress. These patients often require sedation with neuroleptics or benzodiazepines. Hypoactive arousal states such as those occasionally seen in hepatic encephalopathy and hypercapnia are often initially perceived as depressed or demented states. The clinical course of delirium in any particular patient may include both increased and decreased arousal states. Many such individuals display daytime sedation with nocturnal agitation and behavioral problems (sundowning).

form of auditory and visual illusions. Patients with auditory illusions, for example, might hear the sound of leaves rustling and perceive it as someone whispering about them. Paranoia and sleep phobia may result. Typical visual illusions are that intravenous tubing is a snake or worm crawling into the skin or that a respirator is a truck or farm vehicle about to collide with the patient. The former auditory illusion may lead to tactile hallucinations, but the most common hallucinations in delirium are visual and auditory.

Orientation is often abnormal in delirium. Disorientation in particular seems to follow a fluctuating course, with patients unable to answer questions about orientation in the morning, yet fully oriented by the afternoon. Orientation to time, place, person, and situation should be evaluated in the delirious patient. Generally, orientation to time is the sphere most likely impaired, with orientation to person usually preserved. Orientation to significant people (parents, children) should also be tested. Disorientation to self is rare and indicates significant impairment. The examiner should always reorient patients who do not perform well on this parameter of the Mental Status Examination, and serial testing of orientation on subsequent days is important.

Language and Cognition
Patients with delirium frequently have abnormal production and comprehension of speech. Nonsensical rambling and incoherent speech, may occur. Other patients may be completely mute. Memory may be impaired, especially primary and secondary memory. Remote memory may be preserved, although the patient may have difficulty distinguishing the present from the distant past (Kaplan et al. 1994).

Mood
Patients with delirium are susceptible to rapid fluctuations in mood. Unprovoked anger and rage reactions occasionally occur and may lead to attacks on hospital staff. Fear is a common emotion and may lead to increased vigilance and an unwillingness to sleep because of increased vulnerability during somnolence. Apathy, such as that seen in hepatic encephalopathy, depression, use of certain medications (e.g., sulfamethoxazole [Bactrim]), and frontal lobe syndromes, is common, as is euphoria secondary to medications (e.g., corticosteroids, DDC, zidovudine) and drugs of abuse (phenycyclidine, inhalants).

Neurological Symptoms
Neurological symptoms often occur in delirium. These include dysphagia as seen after a CVA, tremor, asterixis (hepatic encephalopathy, hypoxia, uremia), poor coordination, gait apraxia, frontal release signs (grasp, suck), choreiform movements, seizures, Babinski's sign, and dysarthria. Focal neurological signs occur less frequently.

Sleep-Wakefulness Disturbances
Sleeping patterns of delirious patients are usually abnormal. During the day they can be hypersomnolent, often falling asleep in mid sentence, whereas at night they are combative and restless. Sleep is generally fragmented, and vivid nightmares are common. Some patients may become hypervigilant and develop a sleep phobia because of concern that something untoward may occur while they sleep.

Causes of Delirium
The cause of delirium may lie in intracranial processes, extracranial ones, or a combination of the two. The most common etiological factors are as follows (Francis et al. 1990).

Infection Induced
Infection is a common cause of delirium in hospitalized patients. The usual abnormalities in hematology, serology, and vital signs are abnormal except in persons (elderly, chronic alcohol abusers, chemotherapy patients, those with HIV spectrum disease) who may not be able to mount the typical response. Bacteremia septicemia (especially that caused by gram-negative bacteria), pneumonia, encephalitis, and meningitis are common offenders. The elderly are particularly susceptible to delirium secondary to urinary tract infections.

Metabolic and Endocrine Disturbances
Metabolic causes of delirium include hypoglycemia, electrolyte disturbances, and vitamin deficiency states. The most common endocrine causes are hyperfunction and hypofunction of the thyroid, adrenal, pancreas, pituitary, and parathyroid.

Metabolic causes may involve consequences of diseases of particular organs, such as hepatic encephalopathy resulting from liver disease, uremic encephalopathy, and post-dialysis delirium resulting from kidney dysfunction, and carbon dioxide narcosis and hypoxia resulting from lung disease. The metabolic disturbance or endocrinopathy must be known to induce changes in mental status and must be confirmed by laboratory determinations or physical examination, and the temporal course of the confusion should coincide with the disturbance (Francis et al. 1990). In some individuals, particularly the elderly, brain injured, and demented, there may be a significant lag time between correction of metabolic parameters and improvement in mental state.

Low-Perfusion States
Any condition that decreases effective cerebral perfusion can cause delirium. Common offenders are hypovolemia, congestive heart failure, and other causes of decreased stroke volume such as arrhythmias, and anemia, which decreases oxygen binding. Maintenance of fluid balance and strict measuring of intake and output are essential in the overall management of delirious states.

Intracranial Causes
Intracranial causes of delirium include head trauma, especially involving loss of consciousness, postconcussive states, and hemorrhage; brain infections; neoplasms; and such vascular abnormalities as CVAs, subarachnoid hemorrhage, transient ischemic attacks, and hypertensive encephalopathy.

Postoperative States
Postoperative causes of delirium may include infection, atelectasis, lingering effects of anesthesia, thrombotic and embolic phenomena, and adverse reactions to postoperative analgesia. Patients who have undergone open heart surgery are particularly at risk for microemboli and subsequent
confusion. General surgery in an elderly patient has been reported to be followed by delirium in 10–14% of cases and may reach 50% after surgery for hip fracture (Lipowski 1989, Schneider et al. 2002, Hanson and Galvez-Jimenez 2004).

Sensory and Environmental Changes
Many clinicians underestimate the disorienting potential of an unfamiliar environment. The elderly are especially prone to develop environment-related confusion in the hospital. Individuals with preexisting dementia, who may have learned to compensate for cognitive deficits at home, often become delirious once hospitalized. In addition, the nature of the intensive care unit often lends itself to periods of high sensory stimulation (as during a “code”) or low sensory input, as occurs at night (Kaufman 1990a). Often, patients use such external events as dispensing medication, mealtimes, presence of housekeeping staff, and physicians’ rounds to mark the passage of time. These parameters are often absent at night, leading to increased rates of confusion during nighttime hours (Cameron 1941). Often, manipulating the patient’s environment (see section on treatment) or removing the patient from the intensive care unit can be therapeutic.

Substance Intoxication Delirium
The list of medications that can produce the delirious state is extensive (Table 51–12). The more common ones include such antihypertensives as methyldopa and reserpine, histamine (H₂) receptor antagonists (cimetidine), corticosteroids, antidepressants, narcotics (especially opioid) and nonsteroidal analgesics, lithium carbonate, digitalis, baclofen (Lioresal), anticonvulsants, antihypertensives, colchicine, bronchodilators, benzodiazepines, sedative-hypnotics, and anticholinergics. Of the narcotic analgesics, meperidine can produce an agitated delirium with tremors, seizures, and myoclonus (Slaby and Erle 1993, Cameron 1941). These features are attributed to its active metabolite normeperidine, which has potent stimulant and anticholinergic properties and accumulates with repeated intravenous dosing (Eisendrath et al. 1987, Slaby and Erle 1993). In general, adverse effects of narcotics are more common in those who have never received such agents before (the narcotically naive) or who have a history of a similar response to narcotics.

Lithium-induced delirium occurs at blood levels greater than 1.5 mEq/L and is associated with early features of lethargy, stuttering, and muscle fasciculations (Blass et al. 1988). The delirium may take as long as 2 weeks to resolve even after lithium has been discontinued, and other neurological signs such as stupor and seizures commonly occur. Maintenance of fluid and electrolyte balance is essential in lithium-induced delirium. Facilitation of excretion with such agents as aminophylline and acetazolamide helps, but hemodialysis is often required (Kaplan et al. 1994).

Principles to remember in cases of drug-induced delirium include the facts that (1) blood levels of possibly offending agents are helpful and should be obtained, but many persons can become delirious at therapeutic levels of the drug, (2) drug-induced delirium may be the

---

result of drug interactions and polypharmacy and not the result of a single agent. (3) over-the-counter medications and preparations (e.g., agents containing caffeine or phenylpropanolamine) should also be considered, and (4) delirium can be caused by the combination of drugs of abuse and prescribed medications (e.g., cocaine and dopaminergic antidepressants).

The list of drugs of abuse that can produce delirium is extensive. Some such agents have enjoyed a resurgence after years of declining usage. These include lysergic acid diethylyamide, psilocybin (hallucinogenic mushrooms), heroin, and amphetamines. Other agents include barbiturates, cannabis (especially dependent on setting, experience of the user, and whether it is laced with phencyclidine ["superweed"] or heroin), jimsonweed (highly anticholinergic), and mescaline. In cases in which intravenous use of drugs is suspected, HIV spectrum illness must be ruled out as an etiological agent for delirium.

The physical examination of a patient with suspected illicit drug-induced delirium may reveal sclerosed veins, "pop" scars caused by subcutaneous injection of agents, pale and atrophic nasal mucosa resulting from intranasal use of cocaine, injected conjunctiva, and pupillary changes. Toxicological screens are helpful but may not be available on an emergency basis. Some agents such as cannabis have long half lives so both qualitative and quantitative assays are recommended.

**Substance Withdrawal Delirium**

Alcohol and certain sedating drugs can produce a withdrawal delirium when their use is abruptly discontinued or significantly reduced. Withdrawal delirium requires a history of use of a potentially addicting agent for a sufficient amount of time to produce dependence. It is associated with such typical physical findings as abnormal vital signs, pupillary changes, tremor, diaphoresis, nausea and vomiting, and diarrhea. Patients generally complain of abdominal and leg cramps, insomnia, nightmares, chills, hallucinations (especially visual), and a general feeling of "wanting to jump out of my skin."

Some varieties of drug withdrawal, although uncomfortable, are not life threatening (e.g., opioid withdrawal). Others such as alcohol withdrawal delirium are potentially fatal. Withdrawal delirium is much more common in hospitalized patients than in patients living in the community. The incidence of delirium tremens, for example, is 1% of all those with alcoholism, but 5% of hospitalized alcohol abusers. Improvement of the delirium occurs when the offending agent is reintroduced or a cross-sensitive drug (e.g., a benzodiazepine for alcohol withdrawal) is employed. When treating patients in withdrawal with high doses of benzodiazepines, oxygen saturation levels should be monitored closely, and shorter acting agents (e.g., Lorazepam, Alprazolam, Oxazepam) should be used in those individuals with significant pulmonary or hepatic diseases. The causes of delirium are summarized in Table 51–13.

Assessment
Appropriate workup of delirious patients includes a complete physical, mental status, and neurological examination (Table 51–14).

History taking from the patient, any available family, previous physicians, the old chart, and the patient’s current nurse is essential. Previous delirious states, etiologies identified in the past, and interventions that proved effective should be elucidated. The appropriate evaluation of the delirious patient is reviewed in Figure 51–13.

Differential Diagnosis
Delirium must be differentiated from dementia, because the two conditions may have different prognoses (Lipowski 1982, 1983). In contrast to the changes in dementia, those in delirium have an acute onset (Lipowski 1987). The symptoms in dementia tend to be relatively stable over time, whereas clinical features of delirium display wide fluctuation with periods of relative lucidity. Clouding of consciousness is common in delirium, but demented patients are usually alert. Attention and orientation are more commonly disturbed in delirium, although the latter can become impaired in advanced dementia. Perception abnormalities, alterations in the sleep–wakefulness cycle, and abnormalities of speech are more common in delirium. Most important, a delirium is more likely to be reversible than is a dementia.

Delirium and dementia can occur simultaneously; in fact, the presence of dementia is a risk factor for delirium (Fick et al. 2005). Some studies suggest that about 30% of hospitalized patients with dementia have a superimposed delirium.

Delirium must often be differentiated from psychotic states related to such conditions as schizophrenia or mania and factitious disorders with psychological symptoms. Generally, the psychotic features of schizophrenia are more constant and better organized than are those in delirium, and patients with schizophrenia seldom have the clouding of

Figure 51–13 Evaluation of delirium.
consciousness seen in delirium. The “psychosis” of patients with factitious disorder is inconsistent, and these patients do not exhibit many of the associated features of delirium. Apathetic and lethargic patients with delirium may occasionally resemble depressed individuals, but tests such as EEG distinguish between the two. The EEG demonstrates diffuse slowing in most delirious states, except for the low-amplitude, fast activity EEG pattern seen in alcohol withdrawal (Pro and Wells 1977, Obrecht et al. 1979, Brenner 1985, Lipowski 1987). The EEG in a functional depression or psychosis is normal.

**Treatment**

Once delirium has been diagnosed, the etiological agent must be identified and treated. For the elderly, the first step generally involves discontinuing or reducing the dosage of potentially offending medications. Some delirious states can be reversed with medication, as in the case of physostigmine administration for anticholinergic delirium. However, most responses are not as immediate, and attention must be directed toward protecting the patient from unintentional self-harm, managing agitation and psychotic behavior, and manipulating the environment to minimize additional impairment. Supportive therapy should include fluid and electrolyte maintenance and provision of adequate nutrition. Reorienting the patient is essential and is best accomplished in a well-lit room with a window, clock, and visible wall calendar. Familiar objects from home such as a stuffed animal, favorite blanket, or photographs are helpful. Patients who respond incorrectly to questions of orientation should be provided with the correct answers, and because these individuals often see many consultants, physicians should introduce themselves and state their purpose for coming at every visit. Physicians must take into account that impairments of vision and hearing can produce confusional states, and the provision of appropriate prosthetic devices may be beneficial. Around-the-clock accommodation by hospital-provided “sitters” or family members may be required.

Despite these conservative interventions, the delirious patient often requires pharmacological intervention. The liaison psychiatrist is the most appropriate person to recommend such treatment. The drug of choice for the agitated, delirious patients has traditionally been haloperidol (Haldol) (Gelfand et al. 1992). It is particularly beneficial when given by the intravenous route and some authors have reported using dosages as high as 260 mg a day without adverse effect (Gelfand et al. 1992, Steinhart 1983, Tesar et al. 1985, Fernandez et al. 1988, Carter 1986). Extrapyramidal symptoms may be less common with haloperidol administered intravenously as opposed to orally and intramuscularly (Menza et al. 1987). In general, doses in the range of 0.5–5.0 mg intravenously are used, with the frequency of administration depending on a variety of factors including the patient’s age. An electrocardiogram should be obtained before administering haloperidol. If the QT interval is greater than 450, use of intravenous haloperidol can precipitate an abnormal cardiac rhythm known as Torsades de pointes (Kriwisky et al. 1990, Moss 1993, Glassman and Bigger 2001, Tran et al. 1997, Sipahimalani and Massand 1997, 1998, Graver 2000). Such agents as Quetiapine, Olanzapine, and Risperdone have been used successfully to treat delirium. Newer agents may have lower incidences of dystonias and dyskinesias, but still carry the risk of QT interval prolongation, particularly in patients with electrolyte abnormalities (Glassman and Bigger 2001). Quetiapine and Olanzapine are quite sedating and occasionally a combination of bedtime Olanzapine and “as needed” haloperidol is utilized. Olanzapine may raise blood glucose levels and precipitate weight gain, but is available as a Zydis preparation which is absorbed through the oral mucosa and can therefore be given to patients who are unable to take medications by mouth (Osser et al. 1999, Bettinger et al. 2000). There has been some cases of sudden death in patients simultaneously taking parenteral Lorazepam and parenteral olanzapine so this combination should be avoided. Parenteral forms of ziprasidone and aripiprazole are also available. Whatever antipsychotic is chosen, the patient should be carefully monitored for muscle rigidity, unexplained fever, tremor, and other warning signs of neuroleptic side effects, especially neuroleptic malignant syndrome.

**Outcome of Delirium**

After elimination of the cause of the delirium, the symptoms gradually recede during 3–7 days. Some symptoms in certain populations may take weeks to resolve. The age of the patient and the period of time the patient was delirious affect the symptom resolution time (Kaplan et al. 1994). In general, the patient has a spotty memory for events that occurred during delirium. Comments from the staff (“You’re not as confused today”) or the presence of a sitter or use of wrist restraints, may cause patients to wonder why they required these interventions. Patients who wake up in restraints are often quite distraught wondering what behavior they have engaged in that required them to be tied down. Patient should be reassured that they were not responsible for their behavior while delirious and that no one hates or resents them for the behavior they may have exhibited. As mentioned earlier, delirious patients have an increased risk of mortality in the next year (Weddington 1982). Patients with underlying dementia show residual cognitive impairment after resolution of delirium, and it has been suggested that a delirium may merge into a dementia (Kaplan et al. 1994).

**Amnestic Disorders**

The amnestic disorders are characterized by a disturbance in memory related to the direct effects of a general medical condition or the persisting effects of a substance (First 1994). The memory impairment should interfere with social and occupational functioning and represent a significant decline from the previous level of functioning. The amnestic disorders are differentiated on the basis of the etiology of the memory loss. These disorders should not be diagnosed if the memory deficit is a feature of a dissociative disorder, is
Amnestic Disorder due to… [Indicate the General Medical Condition]

A. The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.

B. The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.

C. The memory disturbance does not occur exclusively during the course of a delirium or a dementia.

D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition (including physical trauma).

Specify if:

Transit: if memory impairment lasts for 1 month or less

Chronic: if memory impairment lasts for more than 1 month

Coding note: Include the name of the general medical condition on Axis I, e.g., 294.0 amnestic disorder due to head trauma; also code the general medical condition on Axis III.

Etiology

The specific causes of amnestic disorders include:

1. Systemic medical conditions such as thiamine deficiency;
2. Brain conditions, including seizures, cerebral neoplasms, head injury, hypoxia, carbon monoxide poisoning, surgical ablation of temporal lobes, electroconvulsive therapy, and multiple sclerosis;
3. Altered blood flow in the vertebral vascular system, as in transient global amnesia; and
4. Effects of a substance (drug or alcohol use and exposure to toxins)

The specific causes of amnestic disorders include:

1. Systemic medical conditions such as thiamine deficiency;
2. Brain conditions, including seizures, cerebral neoplasms, head injury, hypoxia, carbon monoxide poisoning, surgical ablation of temporal lobes, electroconvulsive therapy, and multiple sclerosis;
3. Altered blood flow in the vertebral vascular system, as in transient global amnesia; and
4. Effects of a substance (drug or alcohol use and exposure to toxins)

Conditions that affect the temporal lobes such as herpes infection and Klüver-Bucy syndrome can produce amnesia. Among drugs that can cause amnestic disorders, triazolam (Halcion) has received the most attention, but all

Epidemiology

The exact prevalence and incidence of the amnestic disorders are unknown (Kaplan et al. 1994). Memory disturbances related to specific conditions such as alcohol abuse and head trauma have been studied and these appear to be the two most common causes of amnestic disorders. Kaplan et al. (1984) reported that in the hospital setting the incidence of alcohol-induced amnestic disorders is decreasing while that of amnestic disorders secondary to head trauma is on the rise (Korvath et al. 1989). This may be related to rigorous efforts by hospital personnel to decrease the incidence of iatrogenic amnestic disorder by giving thiamine before glucose is administered.

Substance-Induced Persisting Amnestic Disorder

A. The development of memory impairment as manifested by impairment in the ability to learn new information or the inability to recall previously learned information.

B. The memory disturbance causes significant impairment in social or occupational functioning and represents a significant decline from a previous level of functioning.

C. The memory disturbance does not occur exclusively during the course of a delirium or a dementia.

D. There is evidence from the history, physical examination, or laboratory findings that the memory disturbance is etiologically related to the persisting effects of substance use (e.g., a drug of abuse, a medication).

Code: [specific substance]-induced persisting amnestic disorder:

(291.1 alcohol; 292.83 sedative, hypnotic, or anxiolytic; 292.83 other [or unknown] substance)

Clinical Features

Patients with amnestic disorder have impaired ability to learn new information (anterograde amnesia) or cannot remember material previously learned (retrograde amnesia). Memory for the event that produced the deficit (e.g., a head injury in a motor vehicle accident) may also be impaired (Torres et al. 2001, Garquonine 1991).

Remote recall (tertiary memory) is generally good, so patients may be able to relate accurately incidents that occurred during childhood but not remember what they had for breakfast. As illustrated by such conditions as thiamine amnestic syndrome, immediate memory is often preserved. In some instances, disorientation to time and place may occur, but disorientation to person is unusual.

The onset of the amnesia is determined by the precipitant and may be acute as in head injury or insidious as in poor nutritional states (Nolan et al. 1991). DSM-IV-TR characterizes short-duration amnestic disorder as lasting less than 1 month and long-duration disorder lasting 1 month or longer. Often individual slack insight into the memory deficit and vehemently insist that their inaccurate responses on a Mental Status Examination are correct.

Selected Amnestic Disorders

Blackouts

Blackouts are periods of amnesia for events that occur during heavy drinking (Tarter and Schneider 1976). Typically, a person awakens the morning after consumption and does not remember what happened the night before. Unlike delirium tremens, which is related to chronicity of alcohol abuse, blackouts are more a measure of the amount of alcohol consumed at any one time. Thus, blackouts are common in binge pattern drinkers and may occur the first time a person ingests a large amount of alcohol. Blackouts are generally transient phenomena, but may persist for weeks or months after cessation of drinking. The memory of a particular event is lost forever, however the blackouts will end if the individual stops drinking and avoids those agents such as benzodiazepines that have a cross-sensitivity with alcohol.

They may be produced by agents with cross-sensitivity to alcohol, such as benzodiazepines. Blackouts should not be confused with alcohol-induced dementia, which presents with cortical atrophy on CT scans, associated features of dementia, and a usually irreversible course.

Korsakoff’s Syndrome

Korsakoff’s syndrome is an amnestic disorder caused by thiamine deficiency. Although generally associated with alcohol abuse, it can occur in other malnourished states such as marasmus, gastric carcinoma, and HIV spectrum disease (Reulen et al. 1985, Victor 1987). This syndrome is usually associated with Wernicke’s encephalopathy, which involves ophthalmoplegia, ataxia, and confusion, with all three features of this triad recognized in about one-third of cases. The ocular signs include nystagmus, bilateral lateral rectus palsies, and conjugate nerve palsies. The gait ataxia is likely to be a combination of polyneuropathy and cerebellar damage.

Unlike patients with delirium tremens, those with Wernicke’s are likely to be much less agitated and do not have the autonomic signs common in delirium tremens.

Of patients who survive Wernicke’s encephalopathy, a percentage have Korsakoff syndrome, which is characterized by the inability to recall information (retrograde amnesia), the inability to assimilate new information (anterograde amnesia), decreased spontaneity and initiative and confabulation. Only about 20% of patients who develop Korsakoff’s will fully recover. The prevention of Wernicke’s involves the administration of thiamine before giving glucose in any form. These patients are likely to be hypomagnesemic as well and magnesium should be given unless the patient has severe renal disease or significant cardiac conduction prolongation. Autopsy findings have placed the incidence of Wernicke’s encephalopathy between 0.8% and 2% of the general population. The incidence can be as high as 12% in a population of alcoholics. Pathologically, Wernicke-Korsakoff syndrome has been associated with hemorrhage into the mamillary bodies.

Head Injury

Head injuries can produce a wide variety of neurological and psychiatric disorders, even in the absence of radiological evidence of structural damage. Delirium, dementia, mood disturbances, behavioral disinhibition, alterations of personality, and amnestic disorders may result (Torres et al. 2001). Amnesia in head injury is for events preceding the incident and the incident itself, leading some physicians to consider these patients as having factitious disorders or being malingerers. The eventual duration of the amnesia is related to the degree of memory recovery that occurs in the first few days after the injury (Torres et al. 2001, Garquonine 1991, Saneda and Corrigan 1992). Amnesia after head injury has become a popular plot device in novels and motion pictures, many of which depictions have erroneously suggested that a second blow to the head is curative.

Differential Diagnosis

Amnestic disorders must be differentiated from the less disruptive changes in memory that occur in normal aging,
the memory impairment that is accompanied by other cognitive deficits in dementia, the amnesia that might occur with clouded consciousness in delirium, the stress-induced impairment in recall seen in dissociative disorders, and the inconsistent amnestic deficits caused by factitious disorder. Patients with dementia, for example, will have impairment in other cognitive areas as well as memory. Patients who are delirious will have altered sensorium, adrenergic signs, and abnormalities in other domains including orientation and attention. Patients with dissociative disorders who may have amnesia (as in a fugue state or dissociative amnesia) will have the other DSM-IV-TR criteria associated with that diagnosis. Patients who are feigning a memory loss or have Factitious Disorder with Psychological Features will have “near miss” answers and inconsistent memory loss, along with the other features associated with that diagnosis.

**Treatment**
As in delirium and dementia, the primary goal in the amnesic disorders is to discover and treat the underlying cause. Because some of these conditions are associated with serious psychological states (e.g., suicide attempts by hanging, carbon monoxide poisoning, deliberate motor vehicle accidents, self-inflicted gunshot wounds to the head, and chronic alcohol abuse), some form of psychiatric involvement is often necessary. In the hospital, continuous reorientation by means of verbal redirection, clocks, and calendars can allay the patient’s fears. Supportive individual psychotherapy and family counseling are beneficial.

---

**Clinical Vignette 1**

A 75-year-old woman presented to the emergency room with complaints of memory loss and inability to “think straight.” For the past month, she and her family had noted a marked change in her mental state that “seemed to happen overnight.” She would forget the names of her grandchildren and showed little interest in activities she had previously enjoyed. Apparently, she had been hospitalized twice in the past for depression, but had never exhibited cognitive impairments. On the Mental Status Examination, she exhibited marked psychomotor retardation and a blunted affect. She was oriented only to person and all three spheres of memory were significantly impaired. In fact, she responded to most questions with a shrug of her shoulders and the comment “I don’t know.” As the interview continued she became more frustrated with her inability to perform, and asked the physician to “stop asking all these questions.” She was hospitalized and a complete work-up was initiated.

The evaluation for dementia revealed negative results of drug and heavy metal screening, the absence of any potentially offending medications, normal CT and MRI scans, and a normal EEG. Chemistry assays, hematology, thyroid functions, vitamin studies, serological tests for syphilis, chest radiography, and urinalysis were normal. Psychological testing revealed inconsistent cognitive deficits.

A psychiatric consultation was obtained, and it was recommended that a trial of psychostimulants be undertaken to rule out the possibility of depression as the cause of her cognitive impairment. The following day she received dextroamphetamine 2.5 mg at 7:00 am and 2.5 mg at noon before lunch. She tolerated the medication well, and her dose was increased to 7.5 mg on the second day. By the third day, she demonstrated improvement in her affect, concentration, and attention span, and in subsequent days her cognition improved significantly. Eventually, she had a complete recovery and the methylphenidate was discontinued after 2 months without relapse.

This case illustrates the difficulty in distinguishing dementia from cognitive impairment in depression. Features suggestive of depression included the relatively rapid onset, the patient’s insight into the cognitive deficits, presence of some vegetative signs of depression, absence of an identified medical condition judged to be responsible, pervasive yet inconsistent cognitive deficits, a past history of treatment for depression, and a positive response to a psychostimulant trial. The psychostimulant was chosen because the onset of action is faster than that of the other antidepressant agents. The principle problems encountered in treating a patient such as this are the tendency of physicians to underdiagnose depression in the elderly and the hesitancy of many caregivers to use psychostimulants for the treatment of depression.

---

**Clinical Vignette 2**

A 33-year-old man was referred to the emergency department because of a change in his mental status. According to the family, he had become markedly agitated, paranoid, and, at times, belligerent. In addition, they reported nausea and vomiting for the past 36 hours. Because he appeared by clinical examination and laboratory testing (urinalysis, complete blood count) to be dehydrated, the patient was admitted to the medicine service. A psychiatric consultation was requested on the third hospital day.

On psychiatric evaluation, the patient gave a history of being HIV-positive for 3 years as a result of intravenous drug use. He denied using drugs or alcohol for the past year. Since being diagnosed HIV-positive, he had taken zidovudine and Bactrim daily. This patient also had a history of bipolar disorder that had been stabilized with lithium carbonate. During the interview, the patient was disoriented in all spheres except person. He thought he was at home in his kitchen. He had poor primary and secondary memory and tended to talk about distant events as if they were occurring at the present time. He felt that someone was torturing his daughter and had even wandered down to the basement of the hospital looking for her. There were visual and auditory hallucinations, and physical examination revealed a tremor accentuated with intention, reflex abnormalities, ataxia, and mild aphasia. His therapist and family reported that they had “never seen him like this,” even during past exacerbations of his bipolar disorder.

Laboratory studies showed no signs of acute infection, a CD4+ cell count of 10, a low therapeutic lithium level, and a negative drug screen. Complete blood count and urinalysis values had reverted to normal after hydration. Chest radiography was unremarkable, and CT and MRI scans showed only mild atrophy. Zidovudine, Bactrim, and lithium had been discontinued at the time of admission.

The patient was started on haloperidol with some improvement in his psychotic features, but his overall cognitive state continued to deteriorate. The patient...

A 68-year-old white male was admitted to the hospital for mental status changes. His wife reported that he had been getting increasingly forgetful and argumentative over the past 2 years. At first the changes had been subtle, but in the past few months his cognition and behavior had declined significantly. She felt unable to care for him at home. The patient’s primary care physician had started him on Donepezil about six months ago without much improvement. Once the patient was hospitalized, he became even more agitated and combative and felt that the nurses were trying to kill him. He was started on Valproic acid for behavior control, with as needed doses of lorazepam and risperidone. The lorazepam seemed to make him more agitated and his QTc increased to 500 ms on Risperdal, so both were discontinued. His behavior improved somewhat with the addition of low dose aripiprazole. The dementia workup (looking for other medical causes) was essentially negative, and he only scored a “10” on the Mini Mental Status evaluation. The diagnosis was Alzheimer’s Dementia and since his symptomatology was severe, his physician decided to add memantine at 5 mg a day with plans to gradually increase it to 10 mg twice a day. The combination of Valproic Acid, Aripiprazole as needed, memantine, and Donepezil produced some improvement in his behavior and he was discharged to a nursing facility.

Eventually required nursing home placement. This complicated case illustrates the difficulty in determining the specific diagnostic category for an observed cognitive impairment. Dementia related to HIV disease, acute mania, persisting effects of a substance, delirium, and cognitive impairment (delirium, dementia, mood disturbance) secondary to medication (see Table 51–12) were all considered. Based on his past history, laboratory examination, HIV-positive status, markedly reduced CD4+ cell count, and associated physical findings, the patient was diagnosed as having an acute delirium. Since his cognitive status continued to deteriorate once his metabolic parameters normalized, he was diagnosed with dementia as well, the latter being related to his HIV-spectrum illness.

Introduction

This chapter deals with disorders characterized by mental symptoms that occur due to the direct physiological effect of a general medical condition. In evaluating patients with mental symptoms of any sort, one of the first questions to ask is whether those symptoms are occurring as part of a primary psychiatric disorder or are caused by a general medical condition, and Figure 52–1 presents a decision tree designed to help in making this decision. The first step is to review the history, physical examination, and laboratory tests to see if there is evidence for the presence of a general medical disorder that could plausibly cause the mental symptoms in question. In making this determination, one looks not only for a temporal correlation (e.g., the onset of a psychosis shortly after starting or increasing the dose of a medication), but also keeps in mind well-documented associations between certain mental symptoms (e.g., depression) and certain general medical conditions (e.g., Cushing’s syndrome). If it appears, at this point, that the mental symptoms could indeed be occurring secondary to a general medical condition, the next step involves determining whether or not these symptoms could be better accounted for by a primary psychiatric disorder. For example, consider the case of a 45-year-old man with a history of recurrent major depression, currently euthymic, who begins a course of steroids for asthma and then, within a week, becomes depressed. The steroids are stopped but the depression continues. In this case, if the depression had cleared shortly after stopping the steroids, one might make the case that the depression occurred secondary to the steroid treatment; the persistence of the symptoms, however, argues strongly that this depression represents rather a recurrence of the major depression.

Once it appears that the mental symptoms in question could well directly result from a general medical condition and could not be better accounted for by a primary psychiatric disorder, then it remains to classify these symptoms into one of the specific types noted in Figure 52–1, and to proceed to the appropriate section below. There is also, at the end of the decision tree, a residual category for “unspecified” mental symptoms, and in this chapter two such syndromes, not uncommonly found in consult-liaison work, are included, namely pseudobulbar palsy and the Klüver–Bucy syndrome.

In caring for patients with mental disorders due to a general medical condition, the question arises as to whether or not symptomatic treatment for these mental symptoms should be offered. Figure 52–2 provides a general treatment algorithm designed to help answer this question. First, one must determine whether the mental symptoms demand emergent treatment. Consider, for example, a postictal psychosis characterized by delusions of persecution, which prompt the patient to become assaultive: here, even though the condition itself will eventually resolve spontaneously, symptomatic treatment of the psychosis is required to protect the patient or others. In cases where the mental symptoms do not present an emergency, one looks to whether the underlying general medical condition is treatable or not. For example, in the case of psychosis due to Huntington’s disease, as
the underlying condition is not treatable, one generally proceeds directly to symptomatic treatment. In cases where the underlying condition is treatable, one must make a judgment as to whether, with treatment of the underlying general medical condition, the mental symptoms will resolve at a clinically acceptable rate. Consider, for example, a patient with anxiety due to hyperthyroidism who has just begun treatment with an antithyroid drug. In such a case, the decision as to whether to offer a benzodiazepine as symptomatic treatment for the anxiety depends not only on the severity and tolerability of the anxiety, but also on the expected time required for the antithyroid drug to resolve the hyperthyroidism; here, clearly, considerable clinical judgment is required.

### Psychotic Disorder Due to a General Medical Condition

**Definition**

A psychotic disorder due to a general medical condition is characterized clinically by hallucinations or delusions...
occurring in a clear sensorium, without any associated decrement in intellectual abilities. Furthermore, one must be able to demonstrate, by history, physical examination, or laboratory findings, that the psychosis is occurring on the basis of a general medical disorder.

**Etiology and Pathophysiology**

Of all the causes of psychosis, the most commonly encountered are three primary psychiatric disorders, namely, schizophrenia, schizoaffective disorder, and delusional disorder, each of these being covered elsewhere in this text. Table 52–1 lists the various secondary causes of psychosis, dividing them into those occurring secondary to precipitants (e.g., medications), those occurring secondary to diseases with distinctive features (e.g., the chorea of Huntington’s disease), and finally a group occurring secondary to miscellaneous causes (e.g., cerebral tumors).

Psychosis occurring secondary to precipitants is perhaps the most common form of secondary psychosis. Among the various possible precipitants, substances, that is to say, drugs of abuse, are perhaps the most common, but these are treated in the chapters on stimulants, hallucinogens, phencyclidine, cannabis, and alcohol. After drugs of abuse, various medications are the next most common precipitants, and of the medications listed in Table 52–1, the most problematic are the neuroleptics themselves. It appears that in a very small minority of patients treated chronically with neuroleptics, a “supersensitivity psychosis” (or, as it has also been called, on analogy with tardive dyskinesia, “tardive psychosis”) may occur. Making such a diagnosis in the case of patients with schizophrenia may be difficult, as one may well say that any increase in psychotic symptoms, rather than evidence for a supersensitivity psychosis, may merely represent an exacerbation of the schizophrenia; in the case of patients treated with antipsychotics for other conditions (e.g., Tourette’s syndrome), however, the appearance of a psychosis is far more suggestive, as it could not be accounted for on the basis of the disease for which the neuroleptic was prescribed. Of the dopaminergic drugs capable of causing a psychosis, levodopa is the most common (Celesia and Barr 1970, Fenelon et al. 2000, Moskovitz et al. 1978); although direct-acting dopamine agonists as bromocriptine and leprotile (Serby et al. 1970, Fenelon et al. 1978) and pramipexole (Almeida and Ranjit 2006) may also be at fault, they are much less likely causes than is levodopa itself. The other medications noted in Table 52–1 only very rarely cause a psychosis.

Of the various encephalitides, which may have a psychosis as a sequela, the most classic is encephalitis lethargica (von Economo’s disease) (Fairweather 1947), a disease that, though no longer occurring in epidemic form, may still be seen sporadically. Other encephalitides, such as Herpes simplex encephalitis (1973 Rennick et al. 1973) may also, albeit rarely, have a psychosis as one of their sequelae.

Of the psychoses secondary to diseases with distinctive features, the psychoses of epilepsy are by far the most important, and these may be ictal, postictal, or interictal. Ictal psychoses represent complex partial seizures and are immediately suggested by their exquisitely paroxysmal onset. Postictal psychoses are typically preceded by a “flurry” of grand mal or complex partial seizures and, importantly, are separated from the last of this “flurry” of seizures by a “lucid” interval lasting from hours to days. Interictal psychoses appear in one of two forms, namely, the psychosis of forced normalization and the chronic interictal psychosis. The psychosis of forced normalization appears when...
anticonvulsants have not only stopped seizures but have essentially “normalized” the EEG: a disappearance of the psychosis with the resumption of seizure activity secures the diagnosis. The chronic interictal psychosis, often characterized by delusions of persecution and reference and auditory hallucinations, appears subacutely, over weeks or months, with or without focal signs, but also by its acute onset: infarction of the frontal lobe (Hall and Young 1992), temporal lobe (Peroutka et al. 1982, Thompson and Nielsen 1949), and thalamus (Feinberg and Rapcsak 1989, Johnson and Richardson 1968, Lim et al. 1988, Miguel et al. 1994). The other specific features listed in Table 52–1 are fairly straightforward. In the past, the differential between Huntington’s disease and schizophrenia complicated by tardive dyskinesia was difficult; today, the availability of genetic testing has greatly simplified this diagnostic task.

Of the miscellaneous causes capable of causing psychosis, cerebral tumors are perhaps the most important, with psychosis being noted with tumors of the frontal lobe (Strauss and Keschner 1935), corpus callosum (Murthy et al. 1997), and temporal lobe (Gal 1958, Keschner et al. 1936, Malamud 1967, Strobes 1953, Tucker et al. 1986). Suggestive clinical evidence for such a cause includes prominent headache, seizures, or certain focal signs, such as aphasia. Cerebral infarction is likewise an important cause, and is suggested not only by accompanying focal signs but also by its acute onset: infarction of the frontal lobe (Hall and Young 1992), temporoparietal area (Peroutka et al. 1982, Thompson and Nielsen 1949), and thalamus (Feinberg and Rapcsak 1989) have all been implicated. Neurosyphilis should never be forgotten as a differential possibility in cases of psychosis of obscure origin, and an FTA (fluorescent treponemal antibody) is appropriate in such cases. Vitamin B_12_ deficiency, likewise, should be borne in mind, especially as this may present with psychosis without any evidence of spinal cord or hematologic involvement. The remaining disorders listed in Table 52–1 are extremely rare causes of psychosis, and represent the “zebras” (for those who are unfamiliar with this usage, a “zebra” is a rare but notable syndrome) of this differential listing. Among these “zebras,” however, one is of particular interest, namely velo–cardio–facial syndrome. This genetic disorder, characterized by cleft

palate, cardiovascular malformations and dysmorphic facies (micrognathia and prominent nose), and, often, mental retardation, also appears, in a substantial minority of cases, to cause a psychosis phenotypically very similar to that caused by schizophrenia.

Assessment and Differential Diagnosis
As noted earlier, psychotic disorder due to a general medical condition is a disorder that by definition occurs in a clear sensorium, without any associated decrement in intellectual abilities: both delirium and dementia are commonly accompanied by hallucinations and delusions, but these conditions are clearly distinguished from psychotic disorder due to a general medical condition by the presence of confusion or significant intellectual deficits. When these features are present, one should proceed to the differential for delirium and dementia described in another chapter of this book (see DSM-IV-TR criteria).

In most cases, a thorough history and physical examination will disclose evidence of the underlying cause of the psychosis in question. In those cases, however, where the patient’s symptomatology is atypical for one of the primary causes of psychosis (e.g., schizophrenia), yet the history and physical examination fail to disclose clear evidence for another cause, a “laboratory screen,” as listed in Table 52–2, may be appropriate. Clearly, one does not order all these tests at once, but begins with those most likely, given the overall clinical picture, to be most informative.

**Epidemiology and Comorbidity**

The overwhelming majority of patients with a chronic psychosis have one of the primary disorders, that is, schizophrenia, schizoaffective disorder, or delusional disorder; secondary causes of psychosis are relatively uncommon.

**Course**

This is determined by the underlying cause. For example, whereas a psychosis occurring secondary to a medication, such as a dopaminergic drug, generally clears within days of discontinuation of the drug, the psychosis due to a chronic condition, such as Huntington’s disease, is likewise chronic.

**Treatment**

Treatment, if possible, is directed at the underlying cause. In those cases where such treatment is unavailable or ineffective, or where control of the psychosis is emergently required, neuroleptics are indicated. Although conventional neuroleptics, such as haloperidol, have long been used successfully, newer atypical agents, such as olanzapine or risperidone, may be better tolerated. In general, it is best to start with a low dose (e.g., 2.5 mg of haloperidol, 5 mg olanzapine, or 1 mg of risperidone) with incremental increases, if necessary, performed slowly.

**Clinical Vignette 1**

Ziegler (1930) reported a case of “myxedema madness” in a 48-year-old woman who, at the age of 45 years, had undergone radiation treatment for Grave’s disease. She was treated with thyroid hormone, but eventually became noncompliant. Soon thereafter, “she began to feel that her husband was paying attention to another woman and that he was trying to do away with her by means of gas or the electric chair. During a game at a party in her own home during the holidays in 1928, she refused to sit in a chair designated for her, thinking it might be a plot to kill her. She also felt that her husband was trying to poison her and refused to take desiccated thyroid gland at home on account of such a belief. On several occasions subsequently, when desiccated thyroid hormone was administered in sufficient quantity, at the repeated and urgent request of her physician, the delusions entirely disappeared and she felt so much better that she concluded that it would be foolish to be taking medicine and discontinued taking it. On such occasions, the psychosis would slowly return in the same form as before.”

**Mood Disorder Due to a General Medical Condition**

Mood disorders due to general medical conditions may occur either with depressive features or manic features, and each is covered in turn.

**With Depressive Features**

**Definition**

A mood disorder secondary to a general medical condition with depressive features is characterized by a prominent and persistent depressed mood or loss of interest, and by the presence of evidence, from the history, physical examination, or laboratory tests, of a general medical condition capable of causing such a disturbance. Although other depressive symptoms (e.g., lack of energy, sleep disturbance, appetite change, or psychomotor change) may be present, they are not necessary for the diagnosis.

**Etiology and Pathophysiology**

The overwhelming majority of cases of depression occur as part of one of the primary mood disorders, including major depressive disorder, dysthymic disorder, bipolar disorder, cyclothymic disorder, or premenstrual dysphoric disorder, all of which are covered elsewhere in this text. The various secondary causes of depression are listed in Table 52–3. In utilizing Table 52–3, the first question to ask is whether the depression could be secondary to precipitants.
Of the various possible precipitants, substances of abuse (e.g., as seen in alcoholism or during stimulant withdrawal) are very common causes, and these are treated in their respective chapters. Medications are particularly important; however, it must be borne in mind that most patients are able to take the medications listed in Table 52–3 without untoward effect: consequently, before ascribing a depression to any medication it is critical to demonstrate that the depression did not begin before the medication was begun, and ideally, to demonstrate that the depression resolved after the medication was discontinued. Anticholinergic withdrawal may occur within days after abrupt discontinuation of highly anticholinergic medications, such as benztropine or certain tricyclic antidepressants, and is characterized by depressed mood, malaise, insomnia, and gastrointestinal symptoms such as nausea, vomiting, abdominal cramping, and diarrhea. Poststroke depression is not uncommon, and may be more likely when the anterior portion of the left frontal lobe is involved; although spontaneous remission within a year is the rule (Astrom et al. 1993, Robinson et al. 1987), depressive symptoms, in the meantime, may be quite severe (Lipsey et al. 1986). Both head trauma and whiplash injuries may be followed by depressive symptoms in close to half of all cases.

Depression may occur secondary to diseases with distinctive features, and keeping such features in mind whenever evaluating depressed patients will lead to a gratifying number of diagnostic “pick-ups.” These features are noted in Table 52–3, and are for the most part self-explanatory; depression associated with epilepsy, however, may merit some further discussion. Ictal depressions are, in fact, simple partial seizures whose symptomatology is for the most part restricted to affective changes. The diagnosis of ictal depression is suggested by the paroxysmal onset of depression (literally over seconds); although such simple partial seizures may last only minutes, longer durations, up to months, have also been reported. Interictal depressions, rather than occurring secondary to paroxysmal electrical activity within the brain, occur as a result of long-lasting changes in neuronal activity, perhaps related to “kindling” within the limbic system, in patients with chronically recurrent seizures, either grand mal or, more especially, complex partial (Indaco et al. 1992, Perini et al. 1996). Such interictal depressions are of gradual onset and are chronic.

Depression occurring as part of certain neurodegenerative or dementing disorders is immediately suggested by the presence of other symptoms of these disorders, such as dementia or distinctive physical findings, for example, parkinsonism.

The miscellaneous or rare causes represent, for the most part, the “zebras” in the differential for depression, and should be considered when, despite a thorough investigation, the diagnosis of a particular case of depression remains unclear.
Mood Disorder Due to . . . [Indicate the General Medical Condition]

A. A prominent and persistent disturbance in mood predominates in the clinical picture, and is characterized by either (or both) of the following:

   (1) depressed mood or markedly diminished interest or pleasure in all, or almost all, activities.
   (2) elevated, expansive, or irritable mood.

B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.

C. The disturbance is not better accounted for by another mental disorder (e.g., Adjustment Disorder With Depressed Mood in response to the stress of having a general medical condition).

D. The disturbance does not occur exclusively during the course of a delirium.

E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify type:

**With Depressive Features:** if the predominant mood is depressed but the full criteria are not met for a Major Depressive Episode

**With Major Depressive-Like Episode:** if the full criteria are met (except Criterion D) for a Major Depressive Episode (see p. 327)

**With Manic Features:** if the predominant mood is elevated, euphoric, or irritable

**With Mixed Features:** if the symptoms of both mania and depression are present but neither predominates

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 293.83 Mood Disorder Due to Hypothyroidism. With Depressive Features: also code the general medical condition on Axis III (see Appendix G for codes).

**Coding note:** If depressive symptoms occur as part of a preexisting dementia, indicate the depressive symptoms by coding the appropriate subtype of the dementia if one is available, e.g., 290.21 Dementia of the Alzheimer’s Type. With Late Onset. With Depressed Mood.

Assessment and Differential Diagnosis

Although the foregoing list of possible causes of depression due to a general medical condition is long, utilizing it in the clinical evaluation of depressed patients need not be burdensome. Evidence for most of the precipitants, diseases with distinctive features, and neurodegenerative or dementing disorders will be uncovered in the course of a standard interview and examination and, after using the list a few times, the physician will immediately recognize their diagnostic relevance. The miscellaneous or rare “zebras,” as with zebras in any other branch of medicine, are only considered when one is at the end of one’s diagnostic rope, a situation often reached when patients fail to respond to treatment that, if the diagnosis were correct, should have led to relief, but did not.

Epidemiology and Comorbidity

Depression is the most common of psychiatric symptoms and although, as noted earlier, the vast majority of cases of depression occur as part of one of the primary depressive disorders (most commonly major depressive disorder), depressions due to a general medical condition, in certain settings, should nevertheless, by virtue of their frequency, receive prime diagnostic consideration. Examples include treatment with corticosteroids as in multiple sclerosis or collagen–vascular diseases and cases of cerebral infarction involving the left frontal area.

Course

Most medication-induced depressions begin to clear within days of discontinuation of the offending medication; depression as part of withdrawal from stimulants or anabolic steroids clears within days or weeks, and from anticholinergics, within days. Poststroke depression, as noted above, typically remits within a year. The course of depression secondary to head trauma or whiplash is generally prolonged, though quite variable. Most of the other conditions or disorders in the list are chronic, and depression occurring secondary to them likewise tends to be chronic: exceptions include depression in multiple sclerosis, which may have a relapsing and remitting course (Dalos et al. 1983), corresponding to the appearance and disappearance of appropriately situated plaques.

Treatment

Treatment efforts should be directed at relieving, if possible, the underlying cause. When this is not possible, antidepressants should be considered. Controlled studies have demonstrated the effectiveness of both nortriptyline (Robinson et al. 2000) and citalopram (Anderson et al. 1994) for poststroke depression, and nortriptyline for depression seen in Parkinson’s disease (Anderson et al. 1980). For other secondary depressions, citalopram is probably a good choice, given its benign side-effect profile and notable lack of drug–drug interactions; nortriptyline should be used with caution in patients with cardiac conduction defects (as it may prolong conduction time) and in those at risk for seizures as in head trauma (Wrobleski et al. 1990) as this agent may also lower the seizure threshold.

Clinical Vignette 2

Kraepelin (1913) reported the case of a 40-year-old man who “had been irritable for 2 years, … and he slept badly …. At home, he expressed ideas of sin—that he had made false entries in his books and would be locked up, and was bringing ruin on his friends as well as himself.” The patient was admitted, and, during a hospital interview, Kraepelin described him as follows:

You will see at once that the man, aged 40 years, whom I am bringing before you today is suffering (continues)
Clinical Vignette 2 continued

Kraepelin felt the diagnosis would have been difficult “if the physical examination of the patient had not brought complete enlightenment. We see that not only is the right pupil more dilated than the left, but both are completely inactive to light, although the reaction to distance is maintained.” Kraepelin’s diagnosis was neurosyphilis, a diagnosis made on the basis of finding Argyll Robertson pupils on the routine physical examination. Further history confirmed the diagnosis, revealing, as it did, the occurrence of secondary syphilitic rash some 12 years prior to admission.

With Manic Features

Definition
Mood disorder due to a general medical condition with manic features is characterized by a prominent and persistently elevated, expansive, or irritable mood, which, on the basis of the history, physical or laboratory examinations, can be attributed to an underlying general medical condition. Other manic symptoms, such as increased energy, decreased need for sleep, hyperactivity, distractibility, pressured speech and flight of ideas, may or may not be present.

Etiology and Pathophysiology

The vast majority of cases of sustained, elevated, or irritable mood occur as part of four primary disorders, namely bipolar I disorder, bipolar II disorder, cyclothymic disorder, and schizoaffective disorder (bipolar type). Cases of elevated or irritable mood secondary to other causes (e.g., secondary to treatment with corticosteroids) are much less common. Table 52–4 lists secondary causes of elevated or irritable mood, with these causes divided into categories designed to facilitate the task of differential diagnosis.

In utilizing Table 52–4, the first step is to determine whether the mania could be secondary to precipitants. Substance-induced mood disorder related to drugs of abuse is covered in the relevant substance-related disorders chapters in this textbook. Of the precipitating factors listed in Table 52–4, medications are the most common offenders. Before, however, attributing the mania to one of these medications, it is critical to demonstrate that the mania occurred only after initiation of that medication; ideally, one would

Hyperthyroidism (proptosis, tremor, tachycardia) (Trzepacz et al. 1988)
also want to show that the mania spontaneously resolved subsequent to the medication's discontinuation. Of the medications listed, corticosteroids, such as prednisone, are likely to cause mania, with the likelihood increasing in direct proportion to dose: in one study (Wolkowitz et al. 1990), 80 mg of prednisone produced mania within five days in 75% of subjects. Levodopa is the next most likely cause, and in the case of levodopa the induced mania may be so pleasurable that some patients have ended up abusing the drug (Giovannoni et al. 2000). Anabolic steroid abuse may cause an irritable mania, and such a syndrome occurring in a “bulked up” patients should prompt a search for other clinical evidence of abuse, such as gynecomastia and testicular atrophy (Pope and Katz 1994). Closed head injury may be followed by mania either directly upon emergence from postcoma delirium (Bakchine et al. 1989, Bracken 1987), or after an interval of months (Clark and Davison 1987, Nizamie et al. 1988). Hemodialysis may cause mania, and in one case (Jack et al. 1983) mania occurred as the presenting sign of an eventual dialysis dementia. Encephalitis may cause mania, as, for example, in postinfectious encephalomyelitis (Moskovich et al. 1995, Paskavitz et al. 1995), with the correct diagnosis eventually being suggested by more typical signs such as delirium or seizures. Encephalitis lethargica (Von Economo’s disease; European Sleeping Sickness) may also be at fault, with the diagnosis suggested by classic signs such as sleep reversal or oculomotor paralyses (Hohman 1921). Aspar-tame taken in very high dose caused mania and a seizure in one patient (Walton 1986), and metrizamide myelography prompted mania in another (Kwentus et al. 1984).

Mania occurring secondary to disease with distinctive features is immediately suggested by these features, as listed in Table 52–4. Some elaboration may be in order regarding mania secondary to cerebral infarction. This cause, of course, is suggested by the sudden onset of the clinical disturbance, with the mania being accompanied by various other more or less localizing signs; what is most remarkable here is the variety of structures that, if infarcted, may be followed by mania. Thus, mania has been noted with infarction of the midbrain (Blackwell 1991, Kulisevsky et al. 1995), thalamus (either on the right side [Cummings and Mendez 1984, Bogousslavsky et al. 1988, Kulisevsky et al. 1993] or bilaterally [McGilchrist et al. 1993, Gentilini et al. 1987]), anterior limb of the internal capsule and adjacent caudate on the right (Starkstein et al. 1990), and subcortical white matter or cortical infarction on the right in the frontoparietal (Jampala and Abrams 1983, Starkstein et al. 1988) or temporal (Starkstein et al. 1988) areas. Mania associated with epilepsy may also deserve additional comment. Ictal mania is characterized by its paroxysmal onset, over seconds, and the diagnosis of postictal mania is suggested when mania occurs shortly after a “flurry” of grand mal or complex partial seizures.

Mania occurring as part of certain neurodegenerative or dementing diseases is suggested, in general, by a concurrent dementia, and in most cases the mania plays only a minor role in the overall clinical pictures. Neurosyphilis, however, is an exception to this rule, for in patients with general paresis of the insane (dementia paralytica) mania may dominate the picture.

Of the miscellaneous or rare causes of mania, cerebral tumors are the most important to keep in mind, with mania being noted with tumors of the midbrain (Greenberg and Brown 1985), tumors compressing the hypothalamus (e.g., a craniopharyngioma [Malamud 1977] or a pituitary adenoma [Alpers 1940], and tumors of the right thalamus (Stern and Dancey 1942), right cingulate gyrus (Angelini et al. 1980), or one or both frontal lobes (Gross and Herridge 1988).

Assessment and Differential Diagnosis

In most cases of mania secondary to precipitants, the cause (e.g., treatment with high dose prednisone) is fairly straightforward; in cases secondary to diseases with distinctive features or occurring as part of certain neurodegenerative or dementing diseases, the cause is generally readily discernible if the clinician is alert to the telltale distinctive features (e.g., a Cushingoid habitus) and to the presence of dementia indicating one of the dementing disorders listed in Table 52–4. The miscellaneous or rare causes represent the “zebras” in the differential of secondary mania, and are generally only resorted to when other investigations prove unrewarding.

As a rule, it is very rare for mania to constitute the initial presentation of any of the disease or disorders listed in Table 52–4; thus, other evidence of their presence will become evident during the routine history and physical examination. Exceptions to the rule include neurosyphilis (Binder and Dickman 1980), vitamin B12 deficiency (Goggans 1984), and Creutzfeld–Jakob disease (Lendvai et al. 1999); however, in all these cases continued observation will eventually disclose the appearance of other evidence suggestive of the correct diagnosis. It must always be kept in mind that certain medications (e.g., antidepressants) may precipitate mania in patients with bipolar disorder; in such cases, history will reveal earlier episodes of either depression, or mania, or both and such cases of mania should not be considered secondary.

Epidemiology and Comorbidity

Compared to cases of primary mania (e.g., bipolar disorder), secondary mania is relatively rare. In certain settings, however, secondary mania may be so common as to merit a “top” position on the differential diagnosis; a prime example would be when prednisone is used in high doses, as in the treatment of multiple sclerosis or rheumatoid arthritis.

Course

Most cases of medication-induced mania begin to clear in a matter of days; for other causes, the course of the mania generally reflects the course of the underlying disease.

Treatment

Treatment, if possible, is directed at the underlying cause. In cases where such etiologic treatment is not possible, or not rapidly effective enough, pharmacologic measures are in order. Mood stabilizers, such as lithium or divalproex used in a fashion similar to that for the treatment of mania occurring in bipolar disorder, are commonly used: both lithium (Siegai 1978) and divalproex (Abbas and Styra 1994) are effective in the prophylaxis of mania occurring secondary to prednisone; case reports also support the use of lithium for mania secondary to zidovudine (O’Dowd and McKegney 1988) and divalproex for mania secondary to closed head injury. As between lithium and divalproex, in cases where there is a risk for seizures (e.g., head injury, encephalitis, stroke, or tumors), divalproex clearly is preferable.
In cases where emergent treatment is required, before lithium or divalproex could have a chance to become effective, oral or intramuscular haloperidol or olanzapine, or oral risperidone, may be utilized, again much as in the treatment of mania in bipolar disorder.

### Clinical Vignette 3

Liebson (2000) reported the case of a 53-year-old man with a right thalamic hemorrhage, who presented with headache and left-sided hemiparesis and hemianesthesia. Four days later he displayed significant anosognosia for his hemiparesis; more remarkable, however, was the change in his mood. One week after the stroke his “mood was remarkably cheerful and optimistic . . . he was noted to praise extravagantly the hospital food, and the nurses found him “talkative.” When he arrived on our ward 11 days after the stroke he was flirtatious with female staff and boasted of having fathered 64 children. His girlfriend was surprised when he kissed her in front of the staff because he had never publicly displayed affection before. He reported excellent energy and expansively invited all the staff to his home for Thanksgiving . . . The mania resolved gradually over a 10-week period after (the) stroke.”

### Anxiety Disorder Due to a General Medical Condition with Panic Attacks or with Generalized Anxiety

#### Definition

Pathologic anxiety secondary to a general medical condition may occur in the form of well-circumscribed and transient panic attacks or in a generalized, more chronic form. As the differential diagnoses for these two forms of anxiety are quite different, it is critical to clearly distinguish them.

Panic attacks have an acute or paroxysmal onset, and are characterized by typically intense anxiety or fear, which is accompanied by various “autonomic” signs and symptoms, such as tremor, diaphoresis, and palpitations. Symptoms rapidly crescendo over seconds or minutes and in most cases the attack will clear within anywhere from minutes up to a half-hour. Although attacks tend to be similar to one another in the same patient, there is substantial interpatient variability in the symptoms seen.

Generalized anxiety tends to be of subacute or gradual onset, and may last for long periods of time, anywhere from days to months, depending on the underlying cause. Here, some patients, rather than complaining of feeling anxious per se, may complain of being worried, tense, or ill at ease. Autonomic symptoms tend not to be as severe or prominent as those seen in panic attacks: shakiness, palpitations (or tachycardia), and diaphoresis are perhaps most common.

#### Etiology and Pathophysiology

Panic attacks are most commonly seen in one of the primary anxiety disorders, namely, panic disorder, agoraphobia, specific phobia, social phobia, obsessive–compulsive disorder, or posttraumatic stress disorder, all of which are covered elsewhere in this book. The causes of secondary panic attacks are listed in Table 52–5. Substance-induced anxiety disorder related to drugs of abuse (e.g., cocaine, cannabis, LSD) is covered in the relevant substance-related disorders chapters in this textbook; clozapine has also been associated with panic attacks (Bressan et al. 2000). Partial seizures and paroxysmal atrial tachycardia are both characterized by their exquisitely paroxysmal onset, over a second or two; in addition, paroxysmal atrial tachycardia is distinguished by the prominence of the tachycardia and by an ability, in many cases, to terminate the attack with a Valsalva maneuver. Hypoglycemia is often suspected as a cause of anxiety, but before the diagnosis is accepted, one must demonstrate

**DSM-IV-TR Criteria**

**Anxiety Disorder Due to . . . [Indicate the General Medical Condition]**

A. Prominent anxiety, Panic Attacks, or obsessions or compulsions predominate in the clinical picture.

B. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of a general medical condition.

C. The disturbance is not better accounted for by another mental disorder (e.g., Adjustment Disorder With Anxiety in which the stressor is a serious general medical condition).

D. The disturbance does not occur exclusively during the course of a delirium.

E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

**With Generalized Anxiety:** if excessive anxiety or worry about a number of events or activities predominates in the clinical presentation

**With Panic Attacks:** if Panic Attacks (see p. 395) predominate in the clinical presentation

**With Obsessive–Compulsive Symptoms:** if obsessions or compulsions predominate in the clinical presentation

**Coding note:** Include the name of the general medical condition on Axis I, e.g., 293.89 Anxiety Disorder Due to Pheochromocytoma. With Generalized Anxiety, also code the general medical condition on Axis III (see Appendix G for codes).

the presence of “Whipple’s triad”: hypoglycemia (blood glucose ≤45 mg/dL), typical symptoms, and the relief of those symptoms with glucose. Angina or acute myocardial infarction can present with a panic attack, with the diagnosis being suggested by the clinical setting, for example, multiple cardiac risk factors. A pulmonary embolus, at the moment of its lodgment in a pulmonary artery, may also present with a panic attack, and again here the correct diagnosis is suggested by the clinical setting, for example, situations, such as prolonged immobilization, which favor deep venous thrombosis. Acute asthmatic attacks are suggested by wheezing, and pheochromocytoma by associated hypertension. Parkinson’s disease patients treated with levodopa may experience panic attacks during “off” periods.

Generalized anxiety is most commonly seen in the primary psychiatric disorder, generalized anxiety disorder, and is discussed elsewhere in this book; it may also be an integral part of withdrawal from alcohol and sedative/hypnotics, also discussed elsewhere in this text. The secondary causes of generalized anxiety are listed in Table 52–6. Sympathomimetics and theophylline, as used in asthma and COPD, are frequent causes, as is caffeine and many of the antidepressants. Hyperthyroidism is suggested by heat intolerance and proptosis, and Cushing’s syndrome by the typical Cushingoid habitus (i.e., moon facies, hirsutism, acne, “buffalo hump,” and abdominal striae). Hypocalcemia may be suggested by a history of seizures or tetany. Both chronic obstructive pulmonary disease and congestive heart failure are suggested by marked dyspnea. Stroke and traumatic brain injury may be followed by chronic anxiety, but this is seen in only a minority of these patients.

Assessment and Differential Diagnosis

Should one be fortunate enough to observe a patient during the panic attack, it is critical, in addition to carefully noting the specific symptoms of the attack, to obtain vital signs, auscultate the heart and lungs, perform an EKG, and obtain blood for glucose and toxicology.

In evaluating a patient who complains of chronic anxiety, it is important, before deciding that this is, indeed, a case of pathologic generalized anxiety, to first determine whether or not the patient has a depression, whether it be primary or secondary: depression is often accompanied by anxiety, and such anxiety clears upon adequate treatment of the depression. Assuming that the patient, however, is not depressed, a workup should include the following: auscultation of the heart and lungs; CBC and liver enzymes (looking for the telltale “alcoholic” combination of an elevated mean corpuscular volume and elevated transaminases); thyroid profile; cortisol level and calcium level.

Epidemiology and Comorbidity

Although epidemiologic studies are lacking, the clinical impression is that anxiety secondary to a general medical condition is common.

Course

This is determined by the underlying cause.

Treatment

Treatment is directed at the underlying cause, and this is sufficient for all cases of secondary panic attacks and most cases of secondary generalized anxiety; exceptions include poststroke and posttraumatic brain injury anxiety, and in these cases benzodiazepines have been used with success.

Clinical Vignette 4

Rush et al. (1977) describe a patient with simple partial seizures that manifested as panic attacks. The patient, at the age of 44 years, began to have “attacks of palpitation accompanied by dizziness, faintness and anxiety . . . (which) occurred during wakefulness and sleep, and, if asleep, the patient was awakened by them.” At the age of 49 years, he was evaluated and an electroencephalogram, obtained in between attacks, “revealed mild slowing with intermittent, low-voltage, sharp waves over the right temporal region. Because of the paroxysmal nature of the attacks and the electroencephalographic abnormality, the patient was reevaluated utilizing telemetry.” During telemetry, the patient had an attack: “he was pale and mildly diaphoretic and was tightly gripping his chair . . . no abnormal movements were detected . . . (he) remained fully alert and was not incontinent.” Concurrent with the attack, ictal electroencephalographic activity was observed on the right. At craniotomy a glioma was removed from the right frontal lobe and the attacks subsequently did not recur.

With Obsessive–Compulsive Symptoms

Definition

Obsessions consist of unwanted, and generally anxiety-provoking, thoughts, images, or ideas that repeatedly come to mind despite patients’ attempts to stop them. Allied to this are compulsions, which consist of anxious urges to do or undo things, urges that, if resisted, are followed by rapidly increasing anxiety, which can often only be relieved by giving into the compulsion to act. The acts themselves, which the patients feel compelled to perform, are often linked to an apprehension on the patients’ part that they have done something that they ought not to have done or have left undone something that they ought to have done. Thus, one may feel compelled to repeatedly subject the hands to washing to be sure that all germs have been removed, or to repeatedly go back and check on the gas to be sure that it had been turned off.

</table>

Etiology and Pathophysiology

In the vast majority of cases, obsessions and compulsions occur as part of certain primary psychiatric disorders, including obsessive-compulsive disorder, depression, schizophrenia, and Tourette's syndrome. Those rare instances where obsessions and compulsions are secondary to a general medical condition or medication are listed in Table 52–7.

In most cases, these causes of secondary obsessions or compulsions are readily discerned, as for example, a history of encephalitis, anoxia, traumatic brain injury, or treatment with certain second generation antipsychotics, such as clozapine, olanzapine, or risperidone. Sydenham's chorea is immediately suggested by the appearance of chorea; however, it must be borne in mind that obsessions and compulsions may constitute the presentation of Sydenham's chorea, with the appearance of chorea being delayed for days (Swedo et al. 1989). Ictal obsessions or compulsions, constituting the sole clinical manifestation of a simple partial seizure, may, in themselves, be indistinguishable from the obsessions and compulsions seen in obsessive–compulsive disorder, but are suggested by a history of other seizure types, for example, complex partial or grand mal seizures. Infarction of the basal ganglia or parietal lobe is suggested by the subacute onset of obsessions or compulsions accompanied by “neighborhood” symptoms such as abnormal movements or unilateral sensory changes. Fahr’s syndrome, unlike the foregoing, may be an elusive diagnosis, only suggested perhaps when CT imaging incidentally reveals calcification of the basal ganglia.

Assessment and Differential Diagnosis

Most causes of secondary obsessions and compulsions are picked up on the routine history and physical examination, with the possible exception of ictal cases, and here it is critical to make a close inquiry as to a history of other seizure types: ictal EEGs are not reliable here, as they are often normal in the case of simple partial seizures. In doubtful cases a “diagnosis by treatment response” to a trial of an anticonvulsant may be appropriate.

Epidemiology and Comorbidity

As noted earlier, secondary obsessions and compulsions are relatively rare.

Course

Although the course of obsessions and compulsions due to fixed lesions, such as those seen with head trauma or cerebral infarction, tends to be chronic, some spontaneous recovery may be anticipated over the following months to a year.

Treatment

When treatment of the underlying cause is not possible, a trial of an SSRI, as used for obsessive–compulsive disorder, might be appropriate.

Clinical Vignette 5

Laplane et al. (1984) described the case of a “41-year-old healthy man (who) was stung on the left arm by a wasp. He immediately sustained a convulsive coma for 24 hours, then adopted intense choreic movements … and impairment of gait. These extrapyramidal symptoms diminished over several months … .”

“Two years after the encephalopathy, he began to show stereotyped activities. The most frequent consisted in mental counting, for example, up to twelve or a multiple of twelve, but sometimes it was a more complex calculation. Such mental activities sometimes were accompanied by gestures, such as a finger pacing of the counts. To switch on and off a light for 1 hour or more was another of his most common compulsions. When asked about this behavior he answered that he had to count… that he could not stop it … that it was stronger than him… .”

“Neurological examination showed abnormal movements… . He had a permanent facial rictus with some facial or mandibular movements somewhat resembling tics. With his finger movements it was difficult to distinguish between involuntary or ‘voluntary’ activity associated with mental counting. Walking was a mixture of parkinsonism and choreic disturbances.”

“Standard and sleep EEG were normal. CT scans were performed in the orbito-meatal plane . . . . The main lesions consisted of low density areas bilaterally in the internal part of the lenticular nucleus.”

Mental Conditions Due to a General Medical Disorder Not Elsewhere Classified

Catatonic Disorder Due to a General Medical Condition

Definition

Catatonia exists in two subtypes, namely, stuporous catatonia (also known as the akinetic or “retarded” subtype) and excited catatonia, and each will be described in turn.

Stuporous catatonia is characterized by varying combinations of mutism, immobility, and waxy flexibility; associated features include posturing, negativism, automatic obedience, and “echo” phenomena. Mutism ranges from complete to partial: some patients may mumble or perhaps utter brief, often incomprehensible, phrases. Immobility, likewise, ranges in severity; some patients may lie in bed for long periods, neither moving, blinking, or even swallowing; others may make brief movements, perhaps to pull at a piece of clothing or to assume a different posture. Waxy flexibility,
also known by its Latin name, *cerea flexibilitas*, is characterized by a more or less severe “lead pipe” rigidity combined with a remarkable tendency for the limbs to stay in whatever position they are placed, regardless of whether the patient is asked to maintain that position or not. Posturing is said to occur when patients spontaneously assume more or less bizarre postures, which are then maintained: one patient crouched low with his arm wrapped over his head, another stood with one arm raised high, and the other stuffed inside his belt. Negativism entails a mulish, intractable, and automatic resistance to whatever is expected, and may be either “passive” or “active.” Passively negativistic patients simply fail to do what is asked or expected: if clothes are laid out they will not dress; if asked to eat or take pills, their lips remain frozen shut. Active negativism manifests in doing the opposite of what is expected: if asked to come into the office, the patient may back into the hallway or if asked to open the eyes wide to allow for easier examination, they may cramp the eyes closed. Automatic obedience, as may be suspected, represents the opposite of negativism, with affected patients doing exactly what they are told, even should it place them in danger. Echo phenomena represent a kind of automatic obedience: in echolalia patients simply repeat what they hear and in echopraxia they mimic the gestures and activity of the examiner. It should be noted that in negativism, automatic obedience, and echo phenomena there is nothing natural or fluid about the patient’s behavior. To the contrary, movements are often awkward, wooden, and tinged with the bizarre.

**Excited catatonia** manifests with varying degrees of bizarre, frenzied, and purposeless behavior. Such patients typically keep to themselves: one marched in place, all the while chanting and gesticulating; another tore at his hair and clothing, broke plates in a corner then crawled under the bed where he muttered and thrashed his arms.

**Etiology and Pathophysiology**

Stuporous catatonia, in the majority of cases, occurs as part of such primary psychiatric disorders as schizophrenia, a depressive episode of either major depression or bipolar disorder, or a manic episode of bipolar disorder, and these are discussed elsewhere in this text. The causes of catatonia due to a general medical condition or medications are listed in Table 52–8.

Stuporous catatonia occurring in association with epilepsy is often suggested by a history of grand mal or complex partial seizures. Ictal catatonia is further suggested by its exquisitely paroxysmal onset, and postictal catatonia by an immediately preceding “flurry” of grand mal or complex partial seizures. Psychosis of forced normalization is an interictal condition distinguished by the appearance of symptoms subsequent to effective control of seizures. The chronic interictal psychosis is also, as suggested by the name, an interictal condition, which, however, appears not after seizures are controlled but rather in the setting of ongoing, chronic uncontrolled epilepsy. Of medications capable of causing catatonia, antipsychotics are by far the most common. Viral encephalitis is suggested by concurrent fever and headache: herpes simplex

**Excited Catatonia**

| Viral encephalitis (Penn et al. 1972) |
Epidemiology and Comorbidity

Stuporous catatonia must be distinguished from akinetic mutism and from stupor of other causes. Akinetic mutes (Cairns et al. 1941) appear quite similar to immobile and mute catatonic; akinetic mutes, however, lack such signs as waxy flexibility, posturing, and negativism, all of which are typically seen in catatonia. Stupor of other causes is readily distinguished from catatonic stupor by the salient fact that catatonics remain alert, in stark contrast with the somnolence or decreased level of consciousness seen in all other forms of stupor.

Excited catatonia must be distinguished from mania. Mania is typified by hyperactivity, which at times may be quite frenzied; the difference with catatonia is that patients with mania want to be involved, whereas those with catatonia keep to themselves; as Kraepelin (Bear et al. 1982) noted, in catatonia “the excitement, even when extremely violent, frequently takes place within the smallest space. The patients have not as a rule any tendency to influence their surroundings, but their restlessness exhausts itself in wholly aimless activity.”

Clinical Vignette 6

Lim et al. (1986) described a case of ictal catatonia occurring in the midst of a complex partial seizure. The patient was a 67-year-old man who was brought to the hospital after being confused for two weeks. When examined, he “sat quietly in a chair, with no spontaneous speech or movement. He responded to questions with few words and manifested frequent echolalia and perseveration….”

Definition

The personality of an adult represents a coalescence of various personality traits present in childhood and adolescence, and is generally quite enduring and resistant to change. Thus, the appearance of a significant change in an adult’s personality is an ominous clinical sign and indicates the presence of intracranial pathology. Patients themselves may not be aware of the change; however, to others, who have known the patient over time, the change is often quite obvious: such observers often note that the patient is “not himself” anymore.

In most cases, the change is nonspecific in nature: there may be either a gross exaggeration of hitherto minor aspects of the patient’s personality or the appearance of a personality trait quite uncharacteristic for the patient. Traits commonly seen in a personality change, as noted in DSM-IV-TR, include lability, disinhibition, aggressiveness, apathy, or suspiciousness.

In addition to these nonspecific changes, there are two specific syndromes, which, though not listed in DSM-IV-TR, are well described in the literature, namely, the frontal lobe syndrome and the interictal personality syndrome (also known as the “Geschwind syndrome”).

The frontal lobe syndrome is characterized by a variable mixture of disinhibition, affective changes, perseveration, and apathy. Disinhibition manifests with an overall coarsening of behavior. Attention to manners and social nuances is lost: patients may eat with gluttony, make coarse and crude jokes, and may engage in unwelcome and inappropriate sexual behavior, perhaps by propositioning much younger individuals or masturbating in public. Affective changes tend toward a silly, noninfectious euphoria; depression, however, may also be seen. Perseveration presents with a tendency to persist in whatever task is currently at hand, and patients may repeatedly button and unbutton clothing, open and close a drawer, or ask the same question again and again. Apathy is characterized by a lack of motivation. Though patients may experience some urges or consider some actions, their plans, if they occur at all, often come, as it were, stillborn, and, lacking in motivation, apathetic patients may either never come to the point of action, or, if they do get started, soon find themselves indifferent, after which they give up.

The interictal personality syndrome, a controversial entity (Bear et al. 1982, Rodin and Schmaltz 1984) is said to occur as a complication of longstanding uncontrolled epilepsy, with repeated grand mal or complex partial seizures. The cardinal characteristic of this syndrome is what is known as “viscosity,” (Waxman and Geschwind 1975) or, somewhat more colloquially, “stickiness.” Here, patients seem unable to let go or diverge from the current emotion or train of thought: existing affects persist long after the situation that occasioned them, and a given train of thought tends to extend itself indefinitely into a long-winded and verbose circumstantiality or tangentiality. This viscosity of thought may also appear in written expression as patients display “hypergraphia” producing long and rambling letters or diaries (Hermann et al. 1988). The inability to “let go” may even extend to such simple acts as shaking hands, such that others may literally have to extract their hand to end the handshake. The content of the patient’s viscous speech and writing generally also changes, and tends toward mystical or abstruse philosophical speculations. Finally, there is also a tendency to hypersexuality, with an overall decrease in libido (Blumer 1970, Blumer and Walker 1967).

Etiology and Pathophysiology

A personality change is not uncommonly seen as the prodrome to schizophrenia; however, in such cases the eventual appearance of the typical psychosis will indicate the correct diagnosis.

Personality change of the nonspecific or of the frontal lobe type, as noted in Table 52–9, may occur secondary to precipitants (e.g., traumatic brain injury), secondary to cerebral tumors (especially those of the frontal or temporal lobes), or as part of certain neurodegenerative or dementing disorders.

</table>
Personality change occurring as part of certain neurodegenerative or dementing disorders deserves special mention, for in many instances the underlying disorder may present with a personality change; this is particularly the case with Pick’s disease, fronto-temporal dementia, and Alzheimer’s disease. The inclusion of amyotrophic lateral sclerosis here may be surprising to some, but it is very clear that, albeit in a small minority, cerebral symptoms may not only dominate the early course of ALS, but may even constitute the presentation of the disease. In the case of the other neurodegenerative disorders (i.e., progressive supranuclear palsy, cortico-basal ganglionic degeneration, multiple system atrophy, Huntington’s disease, and Wilson’s disease) a personality change, if present, is typically accompanied by abnormal involuntary movements of one sort or other, such as Parkinsonism, ataxia, or chorea. The lacunar syndrome, occurring secondary to multiple lacunar infarctions affecting the thalamus, internal capsule, or basal ganglia, deserves special mention as it very commonly causes a personality change of the frontal lobe type by interrupting the connections between the thalamus or basal ganglia and the frontal lobe. Normal pressure hydrocephalus is an important diagnosis to keep in mind, as the condition is treatable; other suggestive symptoms include a broad-based shuffling gait and urinary urgency or incontinence. AIDS should be suspected whenever a personality change is accompanied by clinical phenomena suggestive of immunodeficiency, such as thrush. Neuropathy may present with a personality change characterized by slovenliness and disinhibition. Creutzfeldt–Jakob disease may also present with a personality change, and this appears particularly likely with the “new variant” type; the eventual appearance of myoclonus suggests the correct diagnosis.

The miscellaneous causes represent the diagnostic “zebras” in the differential for personality change. Of them two deserve comment, given their treatability: granulomatous angiitis is suggested by prominent headache, and vitamin B12 deficiency by the presence of macrocytosis or a sensory polyneuropathy.

Assessment and Differential Diagnosis
Personality change must be clearly distinguished from a personality disorder. The personality disorders (e.g., antisocial personality disorder, borderline personality disorder), all discussed elsewhere in this book, do not represent a change in the patient’s personality but rather have been present in a lifelong fashion. In gathering a history on a patient with a personality change, one finds a more or less distinct time when the “change” occurred; by contrast, in evaluating a patient with a personality disorder, one can trace the personality traits in question in a more or less seamless fashion back into adolescence, or earlier.

The frontal lobe syndrome, at times, may present further diagnostic questions, raising the possibility of either mania, when euphoria is prominent, or depression, when apathy is at the forefront. Mania is distinguished by the quality of the euphoria, which tends to be full and infectious in contrast with the silly, shallow, and noninfectious euphoria of the frontal lobe syndrome. Depression may be distinguished by the quality of the patients’ experience: depressed patients definitely feel something, whether it be a depressed mood or simply a weighty sense of oppression. By contrast, the patient with apathy generally feels nothing: the “mental horizon” is clear and undisturbed by any dysphoria or unpleasantness.

MRI scanning is diagnostic in most cases: where this is uninformative, further testing is dictated by one’s clinical suspicions (e.g., HIV testing).

The interictal personality syndrome must be distinguished from a personality change occurring secondary to a slowly growing tumor of the temporal lobe. In some cases, very small tumors, which may escape detection by routine MRI scanning, may cause epilepsy, and then, with continued growth, also cause a personality change. Thus, in the case of a patient with epilepsy who develops a personality change, the diagnosis of the interictal personality syndrome should not be made until a tumor has been ruled out by repeat MRI scanning.

Epidemiology and Comorbidity
Personality change is common, and is seen with especial frequency after traumatic brain injury and as a prodrome to the dementia occurring with such neurodegenerative disorders as Pick’s disease, fronto-temporal dementia, and Alzheimer’s disease.

Course
This is determined by the underlying cause; in the case of the interictal personality syndrome it appears that symptoms persist even if seizure control is obtained.

Treatment
Treatment, if possible, is directed at the underlying cause. Mood stabilizers (e.g., carbamazepine) may be helpful for lability and disinhibition. Antipsychotics (e.g., a second generation agent such as quetiapine) may be helpful with suspiciousness and may also attenuate disinhibition. Antidepressants (e.g., an SSRI) may relieve depressive symptoms. Regardless of which agent is chosen, it is prudent, given the general medical condition of many of these patients, to “start low and go slow.” In many cases, some degree of supervision will be required.
Clinical Vignette 7

Moersch (1925) described a 54-year-old man in whom, three months earlier, “a gradual mental change had been observed. The patient lost his ambition and interest in work . . . he became careless . . . and seemed little concerned about his shortcomings. For two weeks before his examination he had been content to sit aimlessly at home, or to play with his children. He voided at any time and even defecated in his clothes . . . . During general examination, the patient was indifferent and aimless, would sit and look at a newspaper, which might be upside down. He was oriented in all spheres, and his attention might be held for a few moments when aroused. He would follow his son about in a fairly good-natured manner, but always object to being examined, saying that he was not sick. He showed considerable perseveration, repeating movements at times for long periods. For example, one evening he sat before a wash bowl for over a half-hour, turning the faucets on and off.”

This patient’s frontal lobe syndrome, manifest with apathy, disinhibition, and perseveration, constituted the presentation of a tumor of the anterior portion of the corpus callosum, to which the patient eventually succumbed.

Mental Disorder Not Otherwise Specified Due to a General Medical Condition

This is a residual category in DSM-IV-TR for those clinical situations in which the mental disorder occurring secondary to a general medical condition does not fall into one of the specific categories described earlier. Of these various disorders, two are worthy of detailed description, namely, pseudobulbar palsy and the Klüver–Bucy syndrome. Both disorders are commonly seen in dementia clinics, and their occurrence often prompts a request for psychiatric consultation.

Pseudobulbar Palsy

Definition

When fully developed, this syndrome is characterized by emotional incontinence (also known as “pathological laughing and crying”), dysarthria, dysphagia, a brisk jaw-jerk and gag reflex, and difficulty in protruding the tongue (Langworthy and Hesser 1940).

The most remarkable aspect of the syndrome is the emotional incontinence. Here, patients experience uncontrollable paroxysms of laughter or crying, often in response to minor stimuli, such as the approach of the physician to the bedside (Lieberman and Benson 1977). Importantly, despite the strength of these outbursts, patients do not experience any corresponding sense of mirth or sadness; some may attempt to stop the emotional display, only to become acutely distressed at their inability to do so: one patient, who experienced “gales of laughter” whenever he attempted to speak, “felt foolish and ashamed, and had tears in his eyes because he could not ‘control the laughter’” (Davison and Kelman 1939). Some may go out of their way to avoid having these paroxysms: in one case, described by Wilson (1924), the patient “used to walk about the hospital with his eyes glued to the ground (because) if he so much as raised them to meet anyone else’s gaze he was immediately overcome by compulsory laughter, which sometimes lasted for 4 or 5 minutes."

Etiology and Pathophysiology

Pseudobulbar palsy results from bilateral interruption of corticobulbar fibers (Besson et al. 1991), with this interruption occurring anywhere from the cortex (Davison and Kelman 1939, Wilson 1924) through the centrum semiovale (Ishii et al. 1986) to the internal capsule (Colman 1894) and down to the midbrain and pons (Asfora et al. 1989). Thus “released” from upper motor neuron control, the bulbar nuclei act reflexively, creating, in a sense, a kind of “spasticity” of emotional display. The various disorders capable of causing such a bilateral interruption are listed in Table 52–10.

Vascular disorders are by far the most common cause of bilateral interruption of the corticobulbar tracts, as may be seen with infarctions of the cortex or with lacunar infarctions in the corona radiata or internal capsule. Although in some cases it appears that the syndrome occurs after only one stroke, further investigation typically reveals evidence of a preexisting lesion on the contralateral side, a lesion that had been clinically “silent” (Besson et al. 1991). Other vascular causes includeBinswanger’s disease, characterized by diffuse white matter damage in the centrum semiovale, and CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), characterized by both subcortical infarctions and a widespread leukoencephalopathy.

Of the neurodegenerative disorders associated with pseudobulbar palsy, the most prominent is amyotrophic lateral sclerosis, wherein approximately one half of patients are eventually so affected (Gallagher 1989).

Of the miscellaneous causes, cerebral tumors, which bilaterally compress or invade the brainstem (Achari and Colover 1976, Cantu and Drew 1966, Shaﬁqat et al. 1998), are particularly important.

Assessment and Differential Diagnosis

The diagnosis should be suspected whenever patients present with exaggerated and uncontrollable emotional displays. Lability of affect, as may be seen in mania, is ruled out by the fact that the labile patient, while displaying the affect, also experiences a congruent emotional feeling: by contrast in emotional incontinence the patient often feels nothing, except perhaps consternation at the unmotivated and uncontrollable

</table>
emotional display. Inappropriate affect, as may be seen in schizophrenia, is similar to emotional incontinence in that patients with schizophrenia may not experience any corresponding feeling: in schizophrenia, however, one sees other accompanying symptoms, such as mannerisms, hallucinations, and delusions, symptoms that are absent in pseudobulbar palsy. “Emotionalism,” as may be seen after strokes, may suggest the diagnosis, especially given the clinical setting; however here, as with lability, patients also experience a concurrent feeling that is congruent with the emotional display.

Findings on the neurologic examination are also helpful. Bilateral interruption of corticobulbar tracts, as noted above, typically leads to cranial nerve dysfunction with dysarthria, dysphagia, and brisk jaw-jerk and gag reflexes. Given the proximity of the corticospinal tracts, one often also finds evidence of long-tract damage, such as hemiplegia or Babinski signs.

MRI scanning is generally diagnostic in cases secondary to vascular lesions, tumors, and multiple sclerosis. Amyotrophic lateral sclerosis is suggested by the gradual progression of upper and lower motor neuron signs and symptoms; progressive supranuclear palsy by the presence of parkinsonism and supranuclear gaze palsy, and Alzheimer’s disease by the long history of a gradually progressive dementia.

Epidemiology and Comorbidity
Pseudobulbar palsy is not uncommon: as noted above, it is found in almost half of patients with amyotrophic lateral sclerosis (Gallagher 1989). It may also be seen in a much smaller, but still clinically significant, proportion of patients with vascular lesions (Besson et al. 1991), Alzheimer’s disease (Starkstein et al. 1995), and multiple sclerosis (Feinstein et al. 1997).

Course
The overall course of the syndrome reflects the course of the etiologic disorder. The appearance of dysphagia, however, is an ominous sign, carrying, as it does, the risk of aspiration.

Treatment
In addition to treating, if possible, the underlying cause, various medications may be used to reduce the severity of the emotional incontinence. In cases in which stroke, both tricyclic and SSRI antidepressants are effective: of the tricyclics, one may use amitriptyline (in doses of 50–75 mg) (Schiffer et al. 1985) or nortriptyline (in doses of 50–100 mg) (Robinson et al. 1993), and of the SSRIs, citalopram (in a dose of 20 mg) (Andersen et al. 1993). In cases due to amyotrophic lateral sclerosis (Brooks et al. 2004) or multiple sclerosis (Panitch et al. 2006), a combination of dextromethorphan (30 mg) and quinidine (30 mg), given twice daily, is also effective: in this preparation quinidine, of itself, is inactive and merely serves to inhibit the metabolism of dextromethorphan. Of all these agents, citalopram is the easiest to use; remarkably, full relief is often obtained in a matter of days.

Clinical Vignette 8
SA Kinnier Wilson (1924) provided a classic example of emotional incontinence following bilateral cerebral infarctions:

“A woman of age 57 years had suffered from left hemiplegia for one year, when a second stroke occurred involving the right side. Ever since the latter, the daughter remarked that her mother had become, as she put it, ‘hysterical,’ laughing and crying at nothing.

“On examination the patient was seen to have a distinctly vacant, apathetic facial expression at rest. She was able to move the facial muscles voluntarily on both sides, though there was slight weakness of the left corner of the mouth. On the slightest stimulus, even when the observer simply came to her bedside, she at once assumed a lugubrious expression, her mouth opened widely, and a long, almost noiseless bout of weeping ensued, lasting for many seconds, even minutes, at a time. During the spasmodic crying, both sides of the face moved equally, and the eyes suffused with tears. Laughing attacks were extremely rare in comparison.”

Klüver–Bucy Syndrome

Definition
In 1939, Klüver and Bucy (1939) noted some striking behavioral changes in monkeys that had been subjected to bilateral temporal lobectomy, and in so doing described the syndrome that now bears their names. Specifically, they described five characteristics, which they named “hypermetamorphosis,” “psychic blindness,” “oral tendencies,” “emotional changes,” and “changes in sexual behavior.” Given that this nomenclature is somewhat idiosyncratic to these authors, some concrete examples, taken from their article, may enable the reader to gain a sense of the syndrome as it appeared in the monkeys.

The hypermetamorphosis of these animals was manifested by “an excessive tendency to take notice of and to attend and react to every visual stimulus…and to contact every object as soon as possible.” Furthermore, this interest in things was indiscriminate: being psychically “blind,” the animals would approach objects “no matter whether they are very large or very small, dead or alive, edible or inedible, moving or stationary...(they) seem to be just as eager to examine the tongue of a hissing snake, the mouth of a cat, faeces, a wire cage or a wagon as a piece of bread.” Once in contact with an object, the “oral tendencies” often became apparent in that the monkeys typically put “the object into the mouth, biting gently, chewing, licking, touching with the lips and smelling it.” Should another, perhaps dangerous, animal have been approached, the “emotional changes” immediately became apparent, in that the monkeys failed to show any “emotional reactions…generally associated with anger and fear”; indeed, “after being attacked and bitten by another animal (they) may approach this animal again and again in an attempt to examine it.” Finally, and in addition to all the foregoing changes, there were “changes in sexual behavior” manifested by an overall “increase in sexual activity” that was “blind,” and could manifest with increased masturbation or an indiscriminant approach to others, regardless of their sex.

Over time, changes in the original nomenclature used to describe the syndrome have been made so as to facilitate clinical practice. Thus, although the term hypermetamorphosis has survived, “psychic blindness” has fallen into disfavor and most authors speak of a kind of “agnosia.” The
“oral tendencies” are now referred to as hyperorality, and the “emotional changes” as “emotional placidity.” Finally, the varied “changes in sexual behavior” are now simply referred to as hypersexuality. Thus, the full syndrome is characterized by hypermetamorphosis, agnosia (albeit of a peculiar kind), hyperorality, emotional placidity, and hypersexuality. Some examples of the syndrome in humans follow.

The first example demonstrates hypersexuality, hyperorality, agnosia, and emotional placidity. The patient was a 31-year-old woman, who, after recovering from a herpes simplex encephalitis, “made inappropriate sexual advances to female attendants, both manually and orally. At home, she was constantly chewing and swallowing, and all objects within reach were placed in her mouth . . . including toilet paper and faeces . . . . Her affect was characterized by passivity and a pet-like compliance with those attending her” (Lilly et al. 1983).

The second example provides examples of hypermetamorphosis, hyperorality, agnosia, and hypersexuality. The patient, a 58-year-old man who had suffered from Alzheimer’s disease for 6 years, “spent much of his time examining ordinary objects such as the doorstep, ashtrays, or spots on the floor. He placed many objects in his mouth and occasionally ate soil from plant containers . . . he rubbed his genitals so frequently that he developed an excoriation on the shaft of his penis” (Lilly et al. 1983).

Finally, there is the case of a 46-year-old man, who, during a complex partial seizure, “was observed grabbing for objects on his bedside table, and he masturbated in front of the nursing staff. He also placed objects in his mouth, chewed on tissue paper, and attempted to drink from his urine container” (Nakada et al. 1984). Here, there are hypermetamorphosis, hypersexuality, hyperorality, and agnosia.

Etiology and Pathophysiology
The various causes of the Klüver–Bucy syndrome are listed in Table 52–11: in each case, bilateral damage or dysfunction of the temporal lobes has occurred. The mechanism of such bilateral damage in the case of precipitants is fairly straightforward. The neurodegenerative disorders listed have a predilection for the temporal lobes, and this is particularly the case in Pick’s disease and fronto-temporal dementia. Indeed, the appearance of the Klüver–Bucy syndrome early in the course of a dementia is a significant diagnostic clue to one of these two disorders; in the case of Alzheimer’s disease, the syndrome, if it does occur, is generally seen only late in the course. Of the miscellaneous causes, an ictal Klüver–Bucy syndrome is suggested by its exquisitely paroxysmal onset and by the occurrence of other symptoms typical for a complex partial seizure, such as confusion, and a postictal Klüver–Bucy syndrome by the history of an immediately preceding generalized seizure. Adrenoleukodystrophy, the last in the list, is an extremely rare cause of the Klüver–Bucy syndrome.

Assessment and Differential Diagnosis
The combination of hyperorality and hypersexuality often brings the patient to medical attention: although the full syndrome presents little diagnostic difficulty, as it is not mimicked by any other condition, partial syndromes, consisting primarily of hypermetamorphosis and hypersexuality, may suggest mania. The differential rests on the presence or absence of pressured speech and activity, findings typical of mania but absent in the Klüver–Bucy syndrome.

Epidemiology and Comorbidity
The full Klüver–Bucy syndrome is, overall, rare; in dementia clinics, however, full or partial Klüver–Bucy syndromes are commonly seen.

Course
The course depends on the underlying cause; in some cases, the syndrome itself may have a fatal outcome, as in Clinical Vignette 9.

Treatment
The underlying cause, if possible, is treated. There are no controlled studies regarding symptomatic treatment; anecdotally, overall improvement has been reported with

**Clinical Vignette 9**

Mendez and Foti (1997) describe a 40-year-old with epilepsy secondary to old infarction of the left temporo-parietal area. Grand mal status epilepticus occurred, lasting several hours, during which the patient sustained anoxic damage to both temporal lobes. Upon recovery from the status, the patient “had a voracious appetite and indiscriminate eating habits, which included paper towels, plants, styrofoam cups, and even feces. At one point, he drank urine from a catheter bag. The patient was no longer his assertive self and had become quite docile. He tended to wander about the ward touching objects or people and made inappropriate comments of a sexual nature . . . On the day of his death . . . he had wandered about the ward picking up whatever he could find and putting it into his mouth . . . (and) had a respiratory arrest after stuffing his mouth with surgical gauze . . . . Neuropathological examination disclosed an old infarction in the left posterior cerebral artery territory, virtual absence of the left anterior temporal lobe, and atrophy of the right parahippocampal gyrus, hippocampus and amygdala.”
carbamazepine, sertraline, and various antipsychotics: should an antipsychotic be used, consideration may be given to a second generation agent such as risperidone or quetiapine.

Substance Dependence and Abuse

Substance use problems occur on a spectrum from use to dependence (see Figure 53–1). It is important to understand this entire spectrum in order to properly diagnose, prevent progression of, and treat an individual patient’s problem. Substance use that does not meet criteria for a disorder may influence management and prognosis of co-occurring disorders, and recent evidence has demonstrated the effectiveness of very brief counseling sessions in reducing use and problems in patients not yet dependent on substances (Saitz 2005).

The definitions of substance abuse and dependence are based on the dependence syndrome of Griffith Edwards (Edwards and Gross 1976). Although this syndrome originally had 10 criteria, the DSM-IV-TR criteria for dependence have been reduced to 7, including tolerance and withdrawal (the first 2 criteria) and a pattern of compulsive use (criteria 3–7). Polysubstance dependence is used when an individual uses at least three substances and only meets three or more dependence criteria when all three substances are considered as a group but not for any single substance. For example, when a young adult has been arrested related to the use of cannabis, cannot stop using cocaine, and drinks alcohol despite making his depression worse. However, he or she does not meet dependence criteria for any of these single substances, when considered alone. The severity of dependence can be indicated by the number of criteria met (from a minimum of three to a maximum of seven) and by whether or not physiological dependence occurs (i.e., whether there is tolerance or withdrawal) because physiological dependence is associated with a higher risk for immediate general medical problems and a higher relapse rate. The five criteria indicating compulsive use alone may define substance dependence if at least three occur at any time in the same 12-month period. Physiological dependence is much more likely with some drugs, such as opioids and alcohol, and is infrequent with other classes of drugs, such as hallucinogens.

This section reviews the application of the dependence syndrome to a variety of abused drugs and uses the number of dependence syndrome criteria met as a measure of severity. Treatment-seeking opioid users are likely to meet most of the dependence syndrome criteria, and therefore their use is at the high end of severity. Cannabis users, in contrast, are likely to meet relatively few dependence syndrome criteria, and therefore their use is of a lesser degree of severity. Individuals with alcohol or cocaine dependence tend to demonstrate a much wider variability in the number of dependence criteria met, with the proportion of patients having relatively low levels of dependence approximately equal to those having extremely high levels of dependence. Thus, the severity of substance dependence is variable depending on the type of drug abused. Some substances such as steroid are of research interest but have not been clearly identified as producing the acute reinforcement or dependence and withdrawal symptoms that characterize the abuse of other substances. The heavy use...
Substance Abuse

A. An amaladapted pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

(1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)

(2) recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)

(3) recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)

(4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for substance dependence for this class of substance.

of anabolic steroids by body builders, with the associated possible medical complications, has raised important public health issues, however.

Substance abuse is a maladaptive pattern of substance use leading to significant adverse consequences manifested by psychosocial, medical, or legal problems or use in situations in which it is physically hazardous that must recur during a 12-month period. Since a diagnosis of substance dependence preempts a diagnosis of abuse, tolerance, withdrawal, and compulsive use are generally not present in individuals with a diagnosis of substance abuse. Since caffeine and nicotine generally do not cause psychosocial or legal problems and since it is not physically hazardous to use caffeine and nicotine, a diagnosis of abuse does not apply to these substances. The two abuse criteria focusing on legal and interpersonal problems are not among the dependence criteria.

Substance Intoxication

Substance intoxication is a reversible substance-specific syndrome with maladaptive behavioral or psychological
Intoxication and Withdrawal Syndromes

Substance Withdrawal is a syndrome due to cessation of, or reduction in, heavy and prolonged substance use. It causes changes developing during or shortly after using the substance. It does not apply to nicotine. Recent use can be documented by a history or toxicological screening of body fluids (urine or blood). Different substances may produce similar or identical syndromes and, in polydrug users, intoxication may involve a complex mixture of disturbed perceptions, judgment, and behavior that can vary in severity and duration according to the abuser's setting when the substances are having their effect. For example, an abuser can take a mixture of stimulants (cocaine) and hallucinogens (phen-cyclidine) at a RAVE party and feel euphoric, happy, full of energy, and dancing with great energy, but when the police visit the party, the abuser will become paranoid, irritable, sometimes violent and behave in almost a completely opposite way while under the influence of the same drugs, but now in a different setting. Concomitant use of some substances, for example cocaine and alcohol are often used to enhance pleasurable characteristics while ameliorating dysphoric effects. It should be noted that physiological intoxication is not in and of itself necessarily maladaptive and would not justify a diagnosis of the DSM-IV-TR category substance intoxication. For example, caffeine-induced tachycardia with no maladaptive behavior does not meet the criteria for substance intoxication.

Substance Intoxication

A. The development of a reversible substance specific syndrome due to recent ingestion of (or exposure to) a substance. Note: Different substances may produce similar or identical syndromes.

B. Clinically significant maladaptive behavioral or psychological changes that are due to the effect of the substance on the central nervous system (e.g., belligerence, mood lability, cognitive impairment, impaired judgment, impaired social or occupational functioning), and develop during or shortly after use of the substance.

C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Substance Withdrawal

A. The development of a substance-specific syndrome due to the cessation of (or reduction in) substance use that has been heavy and prolonged.

B. The substance-specific syndrome causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Phenomenology and Variations in Presentation

The diagnosis of substance abuse and dependence is made by eliciting an appropriate history, performing laboratory tests to confirm drug use, and observing the physiological manifestations of tolerance and withdrawal. A diagnostic decision tree is presented in Figure 53–2.

The phenomenology and variations in presentation among abused substances are related to the wide range of substance-induced states as well as the conditions under which the patient is brought to treatment. The emergency department patient who is acutely intoxicated or suffering from a polydrug overdose can present a wide-ranging and confusing diagnostic picture. Depending on the amount of each drug ingested and the time since ingestion, the likelihood of a life-threatening overdose can be difficult to predict. Similarly, distinguishing substance intoxication or withdrawal from an underlying mood or psychotic disorder, or from chronic anxiety disorders, requires careful observation for a period of several hours to several days, in conjunction with urine toxicological screens, to institute proper decision making.

Many patients who use illicit “street” drugs may not know precisely what drugs they have ingested and certainly will not have a good idea of the precise amount. In addition, patients who are dependent on substances producing significant withdrawal syndromes, such as opioids and alcohol, may have a mixed picture of early intoxication and overdose followed by an evolving withdrawal syndrome; alcohol and sedative withdrawal may produce psychiatric complications (e.g., hallucinations) as well as medical complications (e.g., seizures).

The severity of withdrawal symptoms may, in part, be determined by the setting. For example, studies of opioid-dependent patients have shown that the expression of withdrawal symptoms may be substantially less when no medication treatment is available for symptom relief. As a further example of this phenomenon, individuals with opioid addiction who have been in prison without access to opioids for several years may experience opiate withdrawal when they return to the neighborhoods where they previously used heroin. Thus, they develop withdrawal symptoms without having taken any opiates at all! This conditioned withdrawal phenomenon further supports the importance of setting in the presentation of withdrawal symptoms.

Finally, the issues of motivation for seeking treatment and a tendency to deny substance use can have important influences on the patient’s presentation. The patient who presents for treatment because of dysphoric feelings in the context of drug dependence is likely to articulate the severity of his or her problem adequately and even exaggerate some aspects of present discomfort. In contrast, the automobile driver forced to come to a treatment program because of a driving-while-intoxicated offense is likely to minimize her or his alcohol use or any associated complications.

**Special Issues in the Psychiatric Examination**

Two special issues in the psychiatric examination of substance dependence include (1) the source of information when obtaining the history of substance use and related problems and (2) the management of aberrant behaviors. Information about a patient’s substance use history can be provided not only by the patient but also by employers, family members, and school officials. When patients self-report the amount of substance used, there is a tendency to underreport the severity and duration of use; particularly, if the patient is being referred to treatment by an outside source, such as the family, the employer, or the legal system. Objective verification of the exact amount of substance use is sometimes difficult, but the critical issues in arriving at a diagnosis of substance dependence do not depend on the precise amount of substance used. Tolerance and withdrawal can be assessed independently by using tests such as the naloxone challenge and the barbiturate tolerance test. In
Chapter 53 • General Approaches to Substance and Polydrug Use Disorders

In general, significant others’ estimates of the amount of drug use by the patient can be a good source of data. Standardized assessment tools such as the Alcohol Use Disorders Identification Test (AUDIT) (Bohn et al. 1995), Drug Abuse Screening Test (DAST) (Skinner 1982), and the Addiction Severity Index (ASI) (McLellan et al. 1980) may assist in both the diagnosis and treatment planning. Thus, the initial evaluation of substance abuse and dependence may involve a wider range of interviews than would occur with many other types of psychiatric patients.

Aberrant behaviors potentially requiring management include intoxication, violence, suicide, impaired cognitive functioning, and uncontrolled affective displays. The evaluation of an intoxicated patient can address only a limited number of issues. These issues are primarily related to the safety of the patient and other individuals who may be affected by his or her actions. Thus, a medical evaluation for signs of overdose or major cognitive impairment is critical, with consideration of detaining the patient for several hours or even days if severe complications are evident. Intoxication with sedating drugs such as alcohol can lead to significant motor and cognitive impairment, which would have an impact on a patient’s capacity to drive a motor vehicle. When a patient drives a car to an evaluation and is obviously intoxicated, the psychiatrist has an obligation to prevent the patient from getting back into the driver’s seat of that vehicle until the effects of that drug intoxication have worn off. This may involve contacting the police to restrain the patient from driving at least temporarily. Similar issues of police restraint can arise when an intoxicated patient becomes violent and has threatened to harm his or her employers or family members. Judgment and impulse control may be substantially affected by drugs, but these effects may be temporary, and a short-term preventive intervention may be sufficient to avert substantial harm to the patient or others.

Temporary suicidal behavior may be encountered in a variety of substance addictions, particularly those with alcohol and stimulants. Suicidal ideation may be intense but may clear within hours. During the evaluation session, it is important to elicit the precipitants that led the patient to seek treatment at this time and to keep the evaluation

focused on specific data needed for the evaluation of substance dependence, its medical complications, and any comorbid psychiatric disorders. Many patients spend a great deal of time detailing their drug-abusing careers, but in general these stories do not provide useful material for the evaluation or for future psychotherapeutic interventions. Similarly, the evaluation should not become focused on the affective aspects of a patient’s recent life because affect is frequently used as a defense to avoid discussing issues of more immediate relevance such as precipitants or to act as a pretext for obtaining benzodiazepines or other antianxiety agents from the physician. Substances of abuse have generally been a way of managing affect and these patients need to develop alternative coping strategies.

**Physical Examination and Laboratory Findings**

The physical examination is critical for the assessment of substance addiction, particularly before pharmacotherapy is initiated. Many signs of drug withdrawal require a physical examination and cannot rely entirely on history. Because the general medical complications of substance addiction are also substantial, the most clearly ill patients must have a formal general medical evaluation. Vital signs (blood pressure, pulse, and so on) are an essential beginning, but a full examination of heart, lungs, and nervous system is minimally necessary. Transmissible infectious diseases, such as AIDS, tuberculosis, Hepatitis C, and sexually transmitted infections, are common among illicit drug users and require screening for adequate detection. With alcohol dependence, a wide range of gastrointestinal complications have been described, particularly liver dysfunction. Elevated mean corpuscular volume, thrombocytopenia, and elevations of liver transaminases, amylase, lipase, and triglycerides are common.

Urine toxicological screens can be sensitive for detecting drug use within the previous 3 days for opiates and cocaine. Urine screens for other abused drugs such as cannabis can remain positive for as long as a month in heavy users. A breathalyzer can be used for detecting alcohol use within an 8- to 12-hour period after use. These tests may aid in the diagnosis and management of intoxication and withdrawal, but a nondetectable level of alcohol and drugs does not preclude a diagnosis of substance abuse or dependence. Specific biological tests can also aid in the diagnosis of dependence; for example, a naloxone challenge test assesses opioid dependence by precipitating withdrawal symptoms. Associated medical findings on physical examination include “track marks” in intravenous drug users, nasal damage in intranasal drug users, pulmonary damage in drug smokers, hepatosplenomegaly in alcoholics, and dental caries in opiate users. Opiate users develop dental caries due to the blockade of the pain of toothaches, so that they do not notice dental problems until they are well advanced.

**Differences in Developmental, Gender, and Cultural Presentations**

From a developmental perspective, the most important impact of substance abuse and dependence is in adolescence when substance misuse can disrupt schooling and have important medical consequences because of its direct hormonal effects. For example, opioids can increase prolactin levels and at the same time decrease corticosteroid and testosterone levels. These hormonal effects can have a direct impact on the expression of secondary sex characteristics as well as sexual behaviors during adolescence. Another critical developmental effect is during the gestational period of unborn children to substance using mothers. These children may be born with a significant neonatal withdrawal syndrome from drugs such as opioids or may have behavioral and congenital abnormalities secondary to the substance misuse by their mothers; for example, fetal alcohol syndrome in the infants of mothers who are alcohol dependent during pregnancy and the hyperactivity that has been noted in infants born to cocaine-dependent mothers.

At the other extreme of life, in the geriatric population, substance addiction might have an important iatrogenic contribution. Many chronic debilitating diseases are associated with significant pain and may be treated with opioids. Similarly, sleep disorders in the elderly are often treated with sedatives (such as benzodiazepine and barbiturates) that produce tolerance and dependence. Although most of these patients will not experience patterns of substance abuse, some patients may begin to seek these medications from multiple physicians (so-called doctor shopping), and experience significant psychosocial impairment. Patterns of drinking may change with changing family and work roles. This change of pattern coupled with enhanced physiologic effects of alcohol may lead to falls, cognitive deficits, or late onset alcohol dependence.

Sex differences in the presentation of substance addiction problems can be related to the setting in which these problems are detected. For example, young women may come to the attention of the substance abuse treatment provider during or soon after pregnancy. When a child is born with the fetal alcohol syndrome, the mother should be identified as having a substantial problem with alcohol requiring treatment referral. In contrast, the criminal justice system is more likely to identify substance addiction in males and to insist that they get ongoing treatment as a condition of parole or probation.

Some drug abuse patterns are also more common in women than in men. For example, the phenomenon of sex for crack frequently occurs in female cocaine addiction, but men infrequently obtain cocaine using this approach. Finally, although men are more likely than women to misuse drugs generally, some drugs, such as androgenic steroids, are significantly overrepresented in male drug abusers.

Cultural differences in the presentation of drug addiction can be striking. For example, the use of hallucinogens by Native Americans in religious ceremonies shows none of the abusive characteristics of adolescent hallucinogen addiction in middle-class America. Alcohol use can vary based on the amount of alcohol that is considered culturally acceptable in various geographical settings. Thus, Muslims tend to use no alcohol, but may smoke opium in Middle Eastern countries. Among the French, however, the ingestion of larger amounts of alcohol is more normative and may not reflect alcohol dependence, while opium use would be uncommon. The cultural difference between doctor shopping for sedatives and opioids is considerably different from that associated with buying these same drugs on the illicit street market. Gender and family structure are significant sociodemographic correlates of drug use, with use being,
on average, higher among males than females, and higher among students who do not live with either of their parents than among those who live with at least one of their parents.

Because of the relative lack of information about cultural differences in drug use among adolescents, large empirical studies have begun to address these issues. The Monitoring the Future Project has been used to examine empirically the prevalence, trends and sociodemographic correlates of drug use among nationally representative samples of 8th, 10th and 12th graders from 1975 through 2005. Alcohol is the drug most widely used by youth, followed by tobacco and marijuana. By 12th grade, African American youth have the lowest use of substances, Whites the highest. Heavy drinking was reported by 12% of African American, 33% of White, and 25% of Hispanic students in 2005. Whites have higher use of most illicit substances, but Hispanic youth report more inhalants, stimulants, and heroin (Johnston et al. 2006).

**Differential Diagnosis**

The differential diagnosis of substance-induced intoxication and withdrawal can involve a wide range of psychiatric disorders. Distinguishing substance intoxication and withdrawal from these other disorders is usually facilitated by a structured interview to elicit whether the range of psychiatric symptoms are appropriately timed after the most recent substance use. During acute intoxication in polydrug users, the differential diagnosis might include an acute psychotic disorder, mania, delirium, dementia, or several specific anxiety disorders. Among these anxiety disorders are generalized anxiety disorder, panic disorder, and obsessive-compulsive disorder. Distinguishing these disorders from acute intoxication or withdrawal with a mixture of drugs most frequently requires that the psychiatrist wait 24–72 hours to determine whether the symptoms persist and, therefore, whether they are independent of the drug use. While the DSM-IV-TR criteria for substance-induced disorders suggest waiting for a “substantial period of time” (e.g., about a month) to distinguish various substance-induced disorders from those not related to substance abuse, the introduction of pharmacological treatments such as antidepressants does not require such a lengthy delay. Thus, diagnostic and therapeutic distinctions may be different when evaluating the patient.

A previous history of schizophrenia, bipolar disorder, or other major psychiatric disorder that is consistent with the presenting symptoms may also be helpful in arriving at an accurate diagnosis. When patients present with psychotic or manic behavior during drug intoxication, it may be necessary to use symptomatic treatment such as a benzodiazepine or neuroleptic agent to conduct an examination. Because neuroleptic agents lower the seizure threshold, they are most often used in conjunction with a benzodiazepine or other anticonvulsant. A symptomatic response to these medications should not be considered confirmation of an underlying diagnosis of psychotic disorder, however. Furthermore, some drugs, such as phencyclidine, may produce a sustained psychotic state that lasts longer than the usual 72 hours after acute intoxication.

Antisocial and borderline personality disorders are commonly considered in the differential diagnosis of substance-dependent patients. Many of the behaviors that characterize these personality disorders are also common to the use of illegal and illicit drugs. In establishing these personality disorders, particularly antisocial personality, it is important to ascertain whether the behaviors are independent of the activities needed to obtain drugs. If many of the antisocial or borderline characteristics are specifically tied to the patient’s use of drugs, these characteristics should resolve with drug abstinence and should not be considered diagnostic of a personality disorder.

The symptoms of drug withdrawal frequently overlap with those of depressive disorders, and this differential diagnosis can be particularly difficult. Furthermore, the syndrome of protracted withdrawal can include sleep and appetite disturbance as well as dysphoria that mimics dysthymic disorder and other affective disorders. Some drugs, such as opioids, appear to be minimally psychotoxic and are unlikely to produce affective syndromes. Thus, in heroin dependence, a differential diagnosis can be made several days after completing acute detoxification or while the patient is receiving agonist maintenance. With other drugs, such as stimulants, sedatives and alcohol, depressive symptoms may be more persistent after acute detoxification, which leads to a more difficult differential diagnosis. Thus, conservatively, the psychiatrist should wait 4–6 weeks after acute detoxification to determine a diagnosis of affective disorder in these substance-dependent patients. However, waiting this long is often impractical in the clinical setting where the maintenance of sustained abstinence may depend on relief of depressive symptoms using either medications or psychotherapy. In this regard, clinical compromises are addressed in subsequent chapters.

**Epidemiology**

**Prevalence**

Wide cultural variations in attitudes toward substance consumption have led to widely varying patterns of substance misuse and prevalence of substance-related disorders. Relatively high prevalence rates for the use of virtually every substance occur between the ages of 18 and 24 years, with intoxication being the initial substance-related disorder, usually beginning in the teens. In the United States, it is estimated that 8.1% of the population used at least one illicit drug in 2005, and that 22.7% of the population has engaged in binge drinking according to the 2005 National Survey on Drug Use and Health (SAMHSA 2006). Recent use of marijuana has declined, nonmedical use of prescription medications has increased, while use of cocaine and heroin has remained stable over the last several years. Tolerance and withdrawal require a sustained period of use, and these manifestations of physical dependence for most drugs of abuse typically begin in the 20s and early 30s. Twelve-month prevalence estimates for any substance use disorder range from 8 to 10% (SAMHSA 2006, Kessler et al. 2005). Of the estimated 22.2 million Americans with a substance use disorder, 15.4 million had an alcohol use disorder, 3.6 million a drug use disorder, and 3.3 million had both an alcohol and a drug use disorder (SAMHSA 2006). Although most substance-related disorders are more common in men than in women, sex ratios can vary considerably with different drugs of abuse.
Comorbidity Patterns
Serious psychological distress is considerably more prominent in those who use substances. In 2005, 22% of illicit drug users reported serious psychological distress in comparison to 9.6% of adults who did not use illicit drugs (SAMHSA 2006). In both the Epidemiological Catchment Area study and the National Comorbidity Survey, substance abuse and dependence were the most common comorbid disorders, usually appearing in combination with addictive and anxiety disorders. In the National Comorbidity Survey (Kessler et al. 2005) the lifetime rate of substance abuse was 27% and the rate of comorbid depression among these substance abusers was 19%. Furthermore, 80% of these depressed substance-abusing subjects had more than one psychiatric disorder; only 20% had only one psychiatric disorder. In the Epidemiological Catchment Area study (Regier et al. 1984) 75% of daily substance users had a comorbid psychiatric disorder. In studies of treatment-seeking substance abusers, the rates of other psychiatric disorders are almost uniformly higher than those in community samples, but the rates of excess comorbidity in these abusers vary with the specific abused drug. For example, in the Epidemiological Catchment Area study the lifetime rate of major depression in the community was 7%, whereas the major depression rates for substance users seeking treatment were 54% for opioids, 38% for alcohol, and 24% for cocaine. More recent studies such as the Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) study have focused on adolescents (Kandel et al. 1999). In the MECA study the rates of mood and disruptive behavior disorders are much higher among adolescents with current substance use disorders (SUD) than among adolescents without SUD. Comparison with adult samples suggests that the rates of current comorbidity of SUD with psychiatric disorders are the same among adolescents as adults, but the comorbidity of lifetime disruptive disorders or antisocial personality disorder with SUD is lower among adolescents than among adults.

Course and Natural History
The natural history of substance dependence characteristically follows the course of a chronic relapsing disorder, although a large number of individuals who experiment with potentially abusive drugs in adolescence do not go on to acquire dependence. The initial phase of the natural history of experimenting with drugs has been well described in studies by Kandel (1975) who has used the concept of gateway drug use and its evolution into more serious drug dependence during adolescence and the early 20s. The later phases of dependence are characterized in the 20- to 30-year follow-up studies of individuals with alcoholism and those with opioid addiction by Vaillant (Vaillant 1988, Vaillant 1983, Laub and Vaillant 2000). He has documented the natural history after age 20 years in delinquent boys, which is most closely synonymous with having lifetime conduct disorder using DSM-IV-TR criteria, and found high mortality rates by age 40 years in those delinquent boys who later become substance users. In his most recent studies following 475 delinquent boys and 456 matched nondelinquent comparison boys from age 14 years until age 65 years, he found that 13% of the delinquent and only 6% (N = 28) of the nondelinquent subjects died unnatural deaths. These deaths were significantly associated with abuse of alcohol during adulthood and childhood delinquency, and these two factors completely accounted for the other associations of adult crime, dysfunctional home environment, and poor education with the increased mortality. Thus, using substances may have a critical impact on later health, but having a conduct disorder as a child increases this risk, perhaps due to related behaviors such as unwillingness to seek out appropriate health care. Clearly, these studies open more questions about the interaction of substance abuse and childhood behaviors that may not include substance abuse.

The course of substance dependence is variable and may involve full or partial remission with six course specifiers available in the DSM-IV-TR. In order for a patient with dependence to be considered “in remission,” none of the dependence or abuse criteria can be met for at least 1 month. Remission can then be further characterized as either early (less than 12 months) or sustained (lasting 12 months or longer) and partial (one or more criteria for abuse or dependence have been met) or full (no criteria for dependence or abuse). Because the first year of remission carries a particularly high risk for relapse, it has been chosen as the minimum required time for sustained remission. Two additional specifiers apply for special circumstances, such as when the patient is receiving agonist therapy or is in a controlled environment where access to substances is potentially limited (such as jail or a therapeutic community).

Outcome studies across substance type and treatment setting consistently show decreases in substance use, associated problems, and societal costs. Forty to 60% of treated patients will enter full remission with an additional 15–30% achieving partial remission. The most substantial cost benefits come from reduced crime, increased productivity, and decreased health care costs (McLellan et al. 2000).

Etiology and Pathophysiology
The cause of substance addiction depends on a variety of genetic, neurobiological, psychological, and social environmental factors. Neurobiological factors can overlap with genetic predisposition as well as with the psychological substrates for positive and negative reinforcement by abused substances (Nestler 2000). Finally, environment is critical not only for simply exposure to the abused substances themselves (cocaine is not available in many parts of the rural world), but also because the social supports and community setting often protect against substance abuse and dependence, as well as experimentation itself.

Genetic Factors
Family genetic studies have found rates of substance dependence three to four times higher in identical twins than in dizygotic twins (Cloninger 1999). Although no single genetic marker or specific genetic defect has been confirmed, work has suggested that some alleles associated with variations in the dopamine receptor may be more common in substance-dependent individuals than in those who are not dependent. Similarly, risk factor studies have found that the sons of individuals suffering from alcoholism have a general hyporesponsiveness to alcohol and sedative drugs when compared with the sons of individuals without alcoholism.
Neurobiological Factors
The neurobiological substrates for positive and negative reinforcement by abused substances have been examined in a wide range of animal studies. The neuronal pathways underlying positive reinforcement appear to converge on the dopaminergic pathways leading from the ventral tegmental area in the brain stem to the nucleus accumbens, which is part of the basal ganglia (Spanagel and Weiss 1999). Most drugs of abuse appear to act through this pathway to produce positive reinforcement and reward. Some abused drugs, such as stimulants, affect this pathway directly by increasing the amount of dopamine available to stimulate the cells in the nucleus accumbens. Other drugs, such as opioids, appear to have effects on the dopaminergic cells in the ventral tegmental area through specific opioid receptors and thereby indirectly affect the nucleus accumbens. Human research suggests that the nucleus accumbens itself has few opioid receptors. The reinforcing effects of alcohol and benzodiazepines may be through gamma-aminobutyric acid receptors. These gamma-aminobutyric acid receptors also appear on the dopaminergic cells located in the ventral tegmental area. The positive reinforcing effects of hallucinogenic drugs are less clear. For example, marijuana interacts with a specific cannabinoid receptor that is widely distributed in the brain, and it does not appear to have a direct interaction with the dopaminergic systems in the ventral tegmental area. Other hallucinogenic drugs, such as lysergic acid diethylamide, have critical effects on serotonergic systems, which may act on the nucleus accumbens to facilitate dopamine neurotransmission indirectly. Animal studies delineating these reinforcement pathways in the brain have shown that these systems are important for general hedonic tone and the reinforcing properties not only of abused drugs but also of pleasures derived from activities that are considered healthy alternatives to abusing substances. Thus, interventions targeted at these fundamental neuropathways might also interfere with the pleasures of normal daily living.

The negative reinforcers involved in substance dependence include the relief of withdrawal symptoms (Koob and Le Moa 2001). The neurobiological systems responsible for symptoms of withdrawal are multiply determined. Two brain systems that appear to be particularly important during withdrawal are the noradrenergic system in the locus ceruleus of the brain stem and the dopaminergic system that terminates in the nucleus accumbens. The nucleus accumbens is more broadly a part of the limbic circuit, which generally is associated with mood and emotion.

The role of the locus ceruleus in drug withdrawal has been clearly delineated during opiate withdrawal (Kosten and Hollister 2001). The locus ceruleus contains opioid receptors that inhibit locus activity when exposed to morphine. During opiate withdrawal, the locus has high levels of nerve activity, and this nerve activity appears to result from the release of chronic inhibition of the locus by morphine administration. After chronic morphine inhibition, the second-messenger system (cyclic adenosine monophosphate) hypertrophies. This hypertrophy is expressed as locus hyperactivity when morphine is removed.

After chronic administration of cocaine, opioids, or alcohol, there is an increased stimulation threshold in the nucleus accumbens so that the same level of stimulation in the nucleus produces less positive reinforcement. This might be interpreted as a type of negative reinforcement after chronic drug usage. In summary, at least two and probably more neural circuits are recruited into the negative reinforcement associated with substance dependence and thereby are important pathophysiological factors.

Positive and negative reinforcement may not entirely explain the development and maintenance of addiction and the risk of relapse that continues years after cessation of use. Dopamine projections from the midbrain to the prefrontal cortex appear to be responsible for reward-related learning (Hyman 2005). Dopamine release from drugs such as amphetamine, cocaine, and opioids is significantly larger than that from natural rewards such as food and sex, leading to overlearning and persistence of the memory of the pleasure of drug use and the people, places, and things associated with the experience.

Psychological Factors
Psychological factors related to etiology include high rates of depressive disorders and sensation seeking, which are found in individuals prone to substance addiction. The association of sensation seeking with substance addiction suggests that drugs enhance pleasant sensations, such as a high. However, abused drugs may provide potential control of aggressive impulses, which can be a component of sensation seeking that adolescent abusers often would like to control chemically rather than develop the cognitive abilities needed to control aggression. Whether abused drugs serve as self-medication for individuals with these psychological disturbances (e.g., depression, impulsivity, and poor control of aggression) has not been resolved clearly because the age at onset for major psychiatric disorders, such as depression, is older than the age at onset for substance abuse and dependence (Khantzian 1985). Childhood precursors of substance abuse and dependence, including shy and aggressive behaviors, can also be precursors of later depressive disorders as well as of antisocial personality disorder, the adult expression of aggressive impulsivity.

Social and Environmental Factors
Finally, social factors, including peer and family influences, which are not dependent on genetic inheritance, are important in leading to initial drug exposure. Kandel (1975) has conducted longitudinal studies of “gateway drug” usage by adolescents, and these original concepts have been expanded over the last 25 years to recognize their treatment implications. These gateway drugs are tobacco, alcohol, and marijuana. Adolescents who begin using gateway drugs in their early teens are more likely to have substance dependence in their 20s than are adolescents who begin use in their late teens. Delaying the initiation of these gateway drugs and their associated intoxication by 1–2 years substantially decreases the later risk of the development of substance dependence. This association between early gateway drug use and later dependence may be related to the relatively higher rates of conduct disorder and failure to complete school in those who acquire a substance-related disorder in early adolescence. Life stressors related to peers and family are also possible causative factors in substance dependence and their associated comorbid psychiatric disorders (see Clinical Vignette 1). The treatment implications of this
model have been examined with long-term follow-up data from randomized prevention trials to determine the extent to which participation in a cognitive-behavioral skills-training prevention program has led to less illicit drug use than for untreated controls. In one large-scale study, data were collected by mail from 447 individuals who were contacted after the end of the 12th grade, 6.5 years after the initial pretest. Results indicated that students who received the prevention program (Life Skills Training) during junior high school reported less use of illicit drugs than controls. These results also support the hypothesis that illicit drug use can be prevented by targeting the use of gateway drugs such as tobacco and alcohol when children are entering adolescence (Botvin et al. 2000).

Vulnerability to AIDS was associated with significant posttraumatic stress disorder (PTSD) in a spouse of a patient in our methadone maintenance program. Mr. and Ms. T had both been patients in our methadone maintenance program for more than 2 years. They had stopped using illicit drugs since starting methadone treatment and had restabilized their lives with their two children. He had been working since starting treatment after being unemployed for several months before treatment, and they had been living in a comfortable apartment for almost 2 years. Although he had been intermittently ill during the previous year with seemingly minor infections, these illnesses did not prepare them for his hospitalization with Pneumocystis pneumonia followed by a diagnosis of AIDS. His health deteriorated rapidly, and he died less than 6 months after the diagnosis of AIDS. They had both refused to be tested for human immunodeficiency virus when they entered treatment, and she continued to refuse, even after his diagnosis. They had shared needles when using drugs; thus, the probability that she was also infected was high.

During the 6 weeks just before he died, she experienced some symptoms of anticipatory grief, including difficulty sleeping and loss of appetite. Psychotherapeutic treatments were instituted, and she seemed to respond well. The funeral was upsetting, but she appeared to work through the loss of her husband with a typical, several-week course of grief. Six months later, however, she began using cocaine at the urging of a friend. She was using cocaine about twice a week for 3 weeks when nightmares about her dead husband’s illness recurred, and she lost interest in most activities, including caring for her children. She had classic alarm symptoms of PTSD, including being easily startled, an inability to concentrate, sleeplessness, and avoiding activities that reminded her of his illness. This last symptom was particularly problematic because it meant that she would not get any medical care and continued to refuse testing for AIDS. Because of these disturbing events and the urging of her drug treatment counselor, she stopped using cocaine, but the PTSD symptoms continued.

Treatment for her PTSD involved both psychotherapy and pharmacotherapy. The psychotherapy was focused on the trauma of the loss of her husband as well as her own vulnerability. She was concerned about the impact on her children if she were to get AIDS, but this fear had led to denying the possibility of her own infection and to pulling away emotionally from her children. The psychotherapy was enhanced by pharmacological treatment with the tricyclic antidepressant imipramine. Treatment was at first attempted without this medication, but the patient could not discuss any traumatic material with the therapist. Within 2 weeks after starting the imipramine, she began sleeping and concentrating better and engaging in productive psychotherapy.

This case illustrates several points about the association of stress with substance abuse. First, patients with substance use disorders, particularly heroin addicts, can have substantial stressors in their lives, such as early deaths of spouses and vulnerability to fatal illnesses. Second, they may have problems in adjusting to these stressors, and these problems may be somewhat delayed in presentation (e.g., the PTSD was delayed for 6 months after the actual loss). Third, substance use (e.g., the cocaine use) may be an initial response to a psychological stress, even though this may worsen the stress-related symptoms. Fourth, pharmacological treatments may enhance the psychotherapy needed for these stress-induced disorders. This last point suggests that PTSD may have a neurobiological substrate; this provides a rationale and target for pharmacological interventions with this stress-related disorder.

**Goals**

The most important goal of any treatment is abstinence from the abused drug. Issues of “controlled use” are debated by some psychiatrists, but controlled use is usually not a realistic goal for dependent patients. A critical, first treatment goal with substance addiction is often acute treatment of overdose. A psychiatrist must be aware of specific therapies, such as naloxone for opioid overdose and flumazenil for benzodiazepine or other sedative overdose. The polydrug user often has combined toxicity from drug interactions, such as alcohol with cocaine or prescription medications. For dependence on a drug with a significant withdrawal syndrome such as opioids or alcohol the initial treatment involves either agonist stabilization, such as methadone maintenance, or medical detoxification with benzodiazepines when necessary. After detoxification or stabilization, prevention of relapse may occur through a variety of behavioral or other psychotherapeutic approaches. Reduction in drug use without total abstinence using agonist maintenance (e.g., methadone) may be an early priority, together with the provision of essential social services for legal problems, housing, and food. After stabilization, vocational rehabilitation and various psychotherapeutic issues may be addressed, including the management of affect, such as depression. For patients with psychosis, inpatient treatment or interventions with medication may be required before detoxification can occur.

Other treatment goals include total abstinence and family involvement. Patients often advocate for controlled use of some substances such as alcohol use by the patient receiving methadone maintenance or the continued smoking of marijuana or even tobacco by individuals formerly suffering from alcoholism. This can lead to a serious conflict in treatment goals, and increases the risk of relapse to the primary substance or the development of an additional dependence disorder. Another goal is to change the role of family members from “enablers” or codependents with the substance user to treatment allies. These family members...
need to be engaged in treatment to work as active collaborators in the therapeutic plan for the patient. Although family treatment is commonly applied to many psychiatric disorders, it can have a particularly powerful impact with adolescent substance users to eliminate family behaviors that reinforce the drug taking.

**Standard Treatments**

**Psychiatrist–Patient Relationship**

The first issue in the psychiatrist–patient relationship is approaching the substance user who denies a problem. This patient must be approached in such a way that the substance use problem will become accessible for treatment. This may involve an “intervention,” in which a variety of the significant others and social supports of the user are brought together to confront the potential patient about his or her SUD. Family and employers are important contributors to such an intervention.

Once the substance use problem is clearly identified, a series of other issues arise, including confidentiality versus necessary disclosures, comorbid psychiatric disorders, medical evaluations, and potential for relapse. Patients need to be assured of confidentiality in order to get them to be open with the therapist, since the use of illicit drugs can be associated with a variety of illegal activities. Confidentiality must be balanced against the need to disclose to their family about behaviors that can lead to a relapse of substance use. Psychiatric assessment is critical because of the high rates of depression and the risk of suicide in this population. A full medical assessment generally is essential because of the high rates of infectious and gastrointestinal diseases directly related to substance abuse and dependence. Medical assessment is also essential to determine whether active medical detoxification is necessary. Finally, a psychotherapeutic issue early in treatment may be distinguishing between “slips” and a full relapse. Slips are common in substance users, and patients must be prepared for them and not consider them failures that will inevitably lead to full relapse and dependence. Slips are more fully covered in the section on psychosocial treatments.

**Pharmacotherapy**

Pharmacotherapy can have several roles in substance dependence treatment, including treatment of overdose and acute intoxication (naloxone, flumazenil), detoxification or withdrawal symptom relief (benzodiazepines, clonidine), blockage of drug reinforcement (naltrexone), development of responses to the abused substance (disulfiram), anticonvulsing medications (acamprosate), treatment of psychiatric comorbidity (antidepressants), and substitution agents to produce cross-tolerance and reduce drug craving (methadone and buprenorphine). A key element in the treatment of many dependence-producing drugs is the need for detoxification, which may last from 3 days to as long as 2 weeks. Detoxification is essential if antagonist pharmacotherapies, such as naltrexone for opioid dependence, or aversive agents, such as disulfiram for alcoholism, are to be employed. Conversely, agonist maintenance treatment, such as methadone or buprenorphine for heroin dependence, does not require detoxification before beginning treatment. Using these agonists usually requires regular clinic attendance by the patient and relatively prolonged treatment of 1–2 years, with some patients continuing agonist therapy for up to 20 years.

A treatment decision tree is presented in Figure 53–3 and outlines potential roles for pharmacotherapy and psychotherapy.

**Psychosocial Treatments**

A wide range of psychosocial treatments are available in SUD, ranging from long-term residential treatments (6–8 months) to relatively low-intervention outpatient medication-free treatments with once-weekly hour-long therapy. Most patients with substance dependence will require a more intensive counseling approach than can be delivered in the outpatient setting. Other treatment approaches include
inpatient treatment specifically designed for detoxification and day hospital and evening programs focusing on the prevention of relapse. Clinicians should be familiar with the type of programs available, and the need for continued follow-up and a program of relapse prevention.

Evidence-based psychotherapeutic approaches include twelve-step facilitation (TSF), motivational enhancement therapy (MET), cognitive behavioral therapy (CBT), and contingency contracting. TSF therapy is based on the principles of Alcoholics Anonymous (AA), and key components include peer support, admission of loss of control, and commitment to abstinence. MET bolsters commitment to change by exploring the pros and cons of substance use, and developing discrepancy between the behavior of drinking alcohol and the patient's goals. CBTs including relapse prevention therapy (Somers and Marlatt 1992) assist patients in identifying risk factors for drinking and developing tools to prevent relapse. Contingency contracting, in which various aversive or rewarding contingencies are put in place for periods of up to 6 months to prevent relapse, has been particularly effective in stimulant and opiates dependence.

In Project MATCH, TSF, MET, and CBT were compared in a large cohort of alcohol-dependent subjects, and results demonstrated significant improvement with all three therapies, but no significant differences among treatments (Project MATCH 1997). Referral should be based upon available resources and patient preference. Rehabilitation can be done on an inpatient or an outpatient basis. Matching patients to the most appropriate program is based on severity of addiction, medical and psychiatric comorbidity, and resource availability. A distinction should be made between treatment and participation in a self-help group. Self-help groups are complementary to both intensive psychotherapeutic and pharmacological interventions. AA is readily available and has been of unquestionable value to many people suffering from an addictive disorder. Becoming familiar with the 12 steps of AA by attending an open meeting can familiarize clinicians in understanding more about substance dependence and in referring patients to 12-step programs.

**Special Treatment Features**

**Psychiatric Comorbidity**

Comorbid psychiatric disorders, particularly depressive and anxiety disorders, are extremely common in substance abuse and dependence, with lifetime rates approaching 50% in individuals addicted to opioids. Although the rate of major psychotic disorders among SUD is relatively low, the rate of substance use in patients with schizophrenia or bipolar disorder may be as high as 50%.

Splitting treatment between a mental health clinic and substance abuse clinic can be a significant problem for the coordinated management of the patient with co-occurring disorders. A prominent problem in the management of SUD with comorbid psychiatric disorders is medication management within a substance abuse treatment setting because of limited psychiatric resources. In mental health settings, the need for monitoring, using urine toxicological screens for illicit drugs and breath testing for alcohol, can pose difficult logistic and boundary problems. Integrated treatments have been developed using social skills training combined with relapse prevention behavioral therapies as well as pharmacological adjuncts to either typical or atypical neuroleptics for patients with schizophrenia.

Another special factor in treatment is the relationship between many patients and the legal system—for example, parole, probation, work release programs, or other alternatives to incarceration—because this requires the psychiatrist to report to these agencies. Contingencies must be developed with these patients to clarify the content of this reporting as well as to obtain a specific release of confidentiality so that these reporting requirements can be fulfilled.

### General Medical Comorbidity

Treatment of a comorbid medical condition is essential in SUD because many do not seek medical care and may be seen only by the psychiatrist. The most important current comorbid disorder in SUD is AIDS, which is spread primarily by intravenous drug use but increasingly is also spread through sexual activity between drug users. Other areas of medical comorbidity include vitamin deficiencies, infectious diseases, and gastrointestinal disorders, such as cirrhosis, gastrointestinal bleeding, and peptic and duodenal ulcers. Stimulant users may experience cerebrovascular accidents. Also, dementing disorders need particular consideration in conjunction with alcoholism, inhalant abuse, and sedative dependence. With polysubstance use medical complications can be intensified. For example, use of alcohol and cocaine together produces the metabolite cocaethylene and enhances cardiotoxicity whereas combinations of alcohol and other sedatives can lead to respiratory depression, coma, and death.

### Demographical and Psychosocial Considerations

Substance abusers are often young but seek treatment only after a delay of 5–10 years; the average age of patients presenting for treatment is 32 years. Because most substance use problems develop earlier in life, parenting issues are critical, specifically issues of drug use during pregnancy, which can lead to fetal alcohol syndrome, low birth weight, premature delivery, and opiate withdrawal in infants. Neonatal withdrawal requires specific attention and treatments that differ from adult treatment. Geriatric substance misuse, particularly of prescribed medications, is not well recognized and frequently underdiagnosed. Treatment of these geriatric patients with multiple medical problems and complex medical interactions requires careful monitoring by the psychiatrist.

### Treatment-Refractory Patients

A variety of escalating treatment interventions can be applied to patients who are refractory to treatment. If initial detoxification with outpatient follow-up care is ineffective, several levels of intensified interventions can be applied, such as agonist maintenance with methadone for patients addicted to opioids, disulfiram treatment for patients with alcoholism, and perhaps antidepressants for stimulant use disorders. Further interventions can include residential placement for up to 2 years to enable full psychosocial rehabilitation of refractory patients. (See Clinical Vignette 2 for an illustration of such an escalating intervention, when the outpatient tapering of an abusable medication failed and
Other Substance Use Disorders: Anabolic Steroids and Nitrites

This group of substance-related conditions most notably includes anabolic steroids and nitrite inhalants. These both have psychoactive effects and can have consequences for the individual and broad public health, which suggest that future research may lead to their inclusion in future psychiatric classifications as separate disorders.

In 1988, a survey of male high school seniors showed that anabolic steroids had a lifetime use rate of 6.6% (Buckley et al. 1988). Thus, by the late 1980s widespread abuse of anabolic steroids was occurring among males as well as females. Multiple types of steroid derivatives were being used in order to make the lipid soluble steroids more water soluble and easier to administer than the intramuscular injections that were typically required. Because of this abuse, anabolic steroids were added to Schedule III of the Controlled Substances Act in 1990.

The clinical effects of anabolic steroids are related to a typical “cycle” 4–18 weeks on steroids and 1 month to 1 year off. While taking the steroids the primary effects sought by users are increasing muscle mass and strength, not euphoria. In the context of an adequate diet and significant physical activity, these individuals appear quite healthy, and they are unlikely to appear for treatment of their anabolic steroid use. However, some of the adverse cardiovascular, hepatic, and musculoskeletal effects of steroids as well as virilization in women may bring these users to medical attention. Severe cases of acne can also bring some adolescents to medical attention. Abuse of other psychoactive drugs may occur in up to a third of these steroid users, but generally is relatively low compared to other substance abusers.

Heavy use can increase aggression, change libido and sexual functions, and induce mood changes with occasional psychotic features (Brower et al. 1991, Su et al. 1993). In studies comparing doses of 40–240 mg/day of methyltestosterone in a double blind inpatient trial, irritability, mood swings, violent feelings, and hostility were greater during the high dose period than at baseline. Androgenic steroids’ tendency to provoke aggression and irritability has raised concerns about violence toward family members by abusers. Prospective trials have reported mood disturbances in over 50% of body builders using anabolic steroids, as well as cognitive impairment including distractibility, forgetfulness, and confusion.

Dependence symptoms have included a withdrawal syndrome with common symptoms being fatigue, depressed mood, and desire to take more steroids. Other common dependence symptoms are using the substance more than intended, continuing to use steroids despite problems worsened by its use and the excessive spending of time relating to obtaining steroids. Because few clinical laboratories are equipped to conduct steroid tests and these tests are quite expensive, these signs of dependence and some common laboratory abnormalities are usually used to access the diagnosis.

Anabolic steroid abuse leads to hypertrophied muscles, acne, oily skin, needle punctures over large muscles, hirsutism in females, and gynecomastia in males. Heavy users can also develop edema and jaundice. Common laboratory abnormalities include elevated hemoglobin and hematocrit, elevated low-density lipoprotein cholesterol, elevated liver function tests, and reduced luteinizing hormone levels.

Mental health professionals may have these patients come to their attention due to the excessive aggression, loss of sexual ability, or mood disturbances. Treatment approaches are generally symptomatically oriented toward controlling the depressed mood and the psychotic features, but longer term interventions such as peer counseling by former body builders and group support may be of value.
Nitrite inhalants are sometimes considered within the category of inhalant abuse and produce intoxication with mild euphoria, muscle relaxation, and a change in time perception. Concern has been raised about their impairing immune functioning, a decrease in oxygen-carrying capacity of the blood and toxicity with severe headache, vomiting, and hypotension. No physical dependence or withdrawal syndrome has been described with these drugs, and a fuller discussion of them can be found in the section on inhalants.

Alcohol Dependence
Alcohol Abuse

Definition
Alcohol consumption occurs along a continuum, with considerable variability in drinking patterns among individuals. There is no sharp demarcation between “social” or “moderate” drinking and “problem” or “harmful” drinking. It is clear, however, that as the average daily amount of alcohol consumed and frequency of intoxication increase, so does the incidence of medical and psychosocial problems. The focus of this chapter is the alcohol use disorders which, according to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 1994), include alcohol abuse and alcohol dependence.

Etiology and Pathophysiology
Alcohol dependence is a complex, multifaceted disorder which has long been recognized to run in families. There is substantial evidence from twin research and adoption studies that a major genetic component is operative in the development of dependence. Nonetheless, the disorder is etiologically complex, with a variety of other vulnerability factors (Gelernter 1995). It has been estimated that there is a sevenfold risk of alcohol dependence in first-degree relatives of alcohol-dependent individuals, with male relatives of male alcohol-dependent individuals having the greatest risk for the disorder. However, the majority of alcohol-dependent individuals do not have a first-degree relative who is alcohol dependent. This underscores the fact that the risk for alcohol dependence is also determined by environmental factors, which may interact in complex ways with genetics.

Genetic/Environmental Contributions and Clinical Manifestations
In a review of population-based twin studies of alcohol dependence published since 1992, heritability estimates (i.e., the proportion of risk attributable to genetic factors) ranged between 0.52 and 0.64, with no substantial sex difference (Kendler 2001). One study conducted in Sweden using data from temperance board registration showed that the estimate of the genetic contribution to risk of the disorder was stable across four birth cohorts over a 50-year period, despite a rapidly changing social environment (Kendler et al. 1997).

The majority of adoption studies have shown an excess of alcohol dependence in adopted-away offspring of biological parents (McGue 1994). Among studies conducted in the past 30 years, the risk ratio has varied between 1.6 and 3.6 in males and between 0.5 (an effect statistically indistinguishable from 1 or no effect) and 6.3 in females (McGue 1994).

Despite evidence that a genetic factor is influential in the transmission of alcohol dependence, exactly how risk of the disorder is transmitted remains unknown. Alcohol dependence appears to be a polygenic disorder with multiple genes acting either in additive or interactive ways. Two molecular genetic approaches that have been used to identify the genes that influence risk of alcohol dependence are candidate gene studies and linkage studies. Candidate gene studies are population-level investigations in which genetic loci that code for proteins thought to be important in the etiology of the disorder are examined in samples of unrelated individuals. In this approach, a statistical comparison of allele frequencies at...
the candidate locus is made between affected individuals and control subjects. In contrast, linkage studies are conducted at the family level. Individuals from families that manifest the disorder (or in the case of a putative protective effect, families that do not manifest the disorder) are examined genetically. Statistical methods are applied in an effort to identify regions of chromosomes that may contain disease genes.

Candidate Gene Studies
The best-known example of genetic variation affecting risk for alcohol dependence involves candidate genes that are not directly relevant to alcohol’s neuropharmacologic effects, including variant forms of the alcohol-metabolizing enzymes alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) (Gelernter 1995). The mechanism of this effect depends upon the metabolism of alcohol, first to acetaldehyde by ADH and then to acetaldehyde dehydrogenase. Acetaldehyde is toxic and produces a flushing reaction characterized by a set of uncomfortable symptoms including facial flushing, light-headedness, palpitations, and nausea. Thus, increased metabolism of ethanol or decreased metabolism of acetaldehyde, either of which can result in increased acetaldehyde concentrations, produces an aversive effect which could decrease the risk of alcohol dependence. There is, in fact, evidence that a variant that greatly reduces or eliminates ALDH function (occurring mostly in Asian populations) is protective against alcohol dependence, and ADH variants that increase function may also be protective (Thomasson et al. 1991).

Genes encoding proteins in the serotonergic and opiodergic neurotransmitter systems have also been targeted as candidate genes for alcohol dependence. A polymorphism consisting of a repetitive sequence of base pairs in the promoter region of the serotonin transporter protein (genetic locus SLC6A4) is of particular interest. The allele with the smallest number of repeats, commonly called the “short” (S) allele, has lower transcriptional activity, leading to marked reductions in messenger ribonucleic acid (MRNA) levels, serotonin binding, and serotonin uptake in both platelets and lymphoblasts, compared with the “long” (L) allele (Greenberg et al. 1999). Findings from studies examining whether 5′-HTTLPR alleles are associated with alcohol dependence in humans are not consistent. Similarly studies focusing on the gene encoding the μ-opioid receptor (genetic locus OPRM1) have failed to provide convincing evidence of association to alcohol dependence.

Linkage Studies
Two large linkage studies have been conducted in an effort to identify chromosomal regions that contain genes that modify risk for alcohol dependence. The larger of these two projects, the Collaborative Study on the Genetics of Alcoholism (COGA), includes more than 9,000 adults and nearly 1,500 children and adolescents (Hesselbrock et al. 2001). A genomic scan of the COGA samples showed that chromosomes 1 and 7 each have a region containing one or more genes that increase risk of alcohol dependence (Hesselbrock et al. 2001). In addition, COGA found evidence for a “protective factor” on chromosome 4 (Reich et al. 1998).

A linkage study has also been reported from a sample of 152 subjects belonging to extended pedigrees in a southwestern American-Indian tribe (Long et al. 1998). A genome-wide scan was performed on 172 sibling pairs from this sample. Evidence for linkage to alcohol dependence was obtained for regions on chromosomes 4 and 11. Three closely linked loci on chromosome 4 map onto the Type I ADH gene cluster in proximity to the region on this chromosome that was identified as linked to a “protective factor” by COGA.

These linkage studies, in parallel with candidate gene studies, may help to explain the specific mechanisms involved in the increased risk some individuals have for developing alcohol dependence and the interaction of genetic and environmental factors in its etiology.

Etiological Subtypes of Alcoholics
Another approach to understanding the etiology of alcoholism is to identify distinct subtypes of persons with alcohol dependence. A variety of typologic approaches have been proposed to simplify the diverse phenomena associated with alcoholism (Hesselbrock and Hesselbrock 2006). These include unidimensional approaches based on drinking history, drinking pattern, severity of alcohol dependence, family history of alcoholism, gender, personality style, comorbid psychopathology, cognitive impairment, and sociopathy, as well as multidimensional approaches that combine these characteristics into meaningful clusters. One of the best known of these typologies is the Type 1/Type 2 distinction developed by Cloninger et al. (1981) from studies of adopted sons of Swedish alcoholics (see Table 54–1).

Type 1 alcoholics are characterized by the late onset of problem drinking, rapid development of behavioral tolerance to alcohol, prominent guilt and anxiety related to drinking, and infrequent fighting and arrests when drinking. Cloninger also termed this subtype “milieu-limited,” which emphasizes the etiologic role of environmental factors. In contrast, Type 2 alcoholics are characterized by early onset of an inability to abstain from alcohol, frequent fighting and arrests when drinking, and the absence of guilt and fear concerning drinking. Cloninger postulated that transmission of alcoholism in Type 2 alcoholics was from fathers to sons, hence the term male-limited alcoholism. Differences in the two subtypes are thought to result from differences in three basic personality

(i.e., temperament) traits, each of which has a unique neurochemical and genetic substrate (Cloninger 1987). Type 1 alcoholics are characterized by high reward dependence, high harm avoidance, and low novelty seeking. In contrast, Type 2 alcoholics are characterized by high novelty seeking, low harm avoidance, and low reward dependence.

Babor et al. (1992) used statistical clustering techniques to derive a dichotomous typology (Type A vs. Type B) similar to that proposed earlier by Cloninger. The analysis identified two homogeneous subtypes that may have important implications for understanding the etiology of different forms of alcoholism. Cloninger’s Type 1 alcoholic shares with the Type A alcoholic a later onset of alcohol-related problems and the absence of antisocial characteristics. Cloninger’s Type 2 alcoholic shares with the Type B alcoholic an early onset of alcohol-related problems and the presence of antisocial characteristics, particularly when intoxicated. The Type A/Type B classification has been successful in predicting outcome following alcoholism treatment (Litt et al. 1992). Its relevance to the matching of alcoholics to different psychotherapies has been supported by some studies (Litt et al. 1992) but not by others (Project MATCH Research Group 1997a, b).

Implicit in the subtyping theories that have been developed to explain different clinical varieties of alcoholism is the notion that there are a variety of plausible etiological factors in addition to or mediated by genetic predisposition. Three such factors are pharmacological vulnerability, affective dysregulation, and personality disorder. The evidence for pharmacological vulnerability as an etiological factor is based on studies showing reduced sensitivity to the effects of alcohol in adult children of alcoholics (Schuckit and Smith 1996, Pollock 1992). Other evidence comes from research on the effects of ALDH2, ADH1, and ADH2 polymorphisms in individuals of Asian ancestry in which aversive reactions to the effects of alcohol are associated with reduced risk of alcohol dependence (Thomasson et al. 1993). A second etiological factor is affect dysregulation, which proposes that alcoholism is caused by repeated use of alcohol to ‘self-medicate’ negative affective states such as anxiety and depression. This theory is supported by research indicating strong associations between alcohol problems, mood disorders, and life stress (Kessler et al. 1997, Helzer and Pryzbeck 1988). The third etiological factor that has received considerable research support is deviance proneness or behavioral undercontrol, as indicated by hyperactivity, distractibility, sensation seeking, impulsivity, difficult temperament, and conduct disorder. These conditions are hypothesized to contribute to school failure and association with deviant peers, which then provide a context for heavy drinking and drug use (Sher and Trull 1994, Sher 1991).

In summary, despite considerable progress in the identification of risk factors for alcohol dependence, the interactions among genetic, familial, psychological, interpersonal, and environmental influences remain so complex that there is little consensus about etiology at this time.

Pathophysiology

Neuropharmacology

Taken in large doses, alcohol is considered to have anesthetic or depressive properties. It also has the ability to elicit euphoria when administered in small doses to susceptible persons (Begleiter and Porjesz 1999). This phenomenon may be mediated by direct activation by alcohol of the mesolimbic dopaminergic circuit, particularly the ventral tegmental area (VTA) and the nucleus accumbens (NAc) (Brodie et al. 1999). Anxiolysis and relaxation also appear to be part of the spectrum of the rewarding effects of alcohol, though these effects appear to be mediated by activation of GABAergic neurotransmitter system.

In contrast to other addictive substances (e.g., nicotine, cocaine, and opioids) and despite its significant effect on dopaminergic neurotransmission, the existence of specific alcohol binding sites on neuronal membranes has not been conclusively established. The lack of an alcohol receptor has led to the hypothesis that some alcohol effects, particularly those observed when it is administered at large doses, may be explained by disturbances in fluidity of the bi-layer lipid neuronal membrane. Changes in fluidity of neuronal membranes may affect the structure and function of neurotransmitter receptors and ion channels. However, this hypothesis has failed to explain alcohol-rewarding effects that occur at lower doses.

On the other hand, alcohol administration appears to have effects across the major neurotransmitter systems (i.e., opioidergic, serotonergic, GABAergic, and glutamatergic). These systems are affected by both acute and chronic alcohol administration. They appear to play a major role in mediating the rewarding effects of alcohol by modulating the firing of dopaminergic neurons in the VTA and the release of dopamine in the NAc.

Opioidergic Neurotransmission

Findings derived from animal models of alcoholism support a relationship between alcohol administration and opioidergic neurotransmission. Hypothalamic synthesis, release, and binding of endogenous opioids such as beta-endorphin and enkephalin to μ-opiate receptors have been shown to be stimulated by alcohol administration (Eskelson et al. 1980). Disturbances in opioidergic neurotransmission have been reported among alcoholic patients and their unaffected adult children (i.e., paternal history–positive or PHP, Topel 1988). Both groups show lower plasma and cerebrospinal fluid (CSF) concentrations of beta-endorphin than adult children of nonalcoholic subjects (i.e., paternal history–negative or PHN; Gianoulakis et al. 1989), and after alcohol administration, PHP individuals show a greater increase or normalization of their beta-endorphin levels (Gianoulakis et al. 1989, 1996). These findings suggest that an inherited or acquired deficiency in endogenous opioid activity may be present among the offspring of alcoholics. This deficiency might lead them to drink to remediate this deficiency (opioid deficiency hypothesis; Gianoulakis et al. 1996). Further support for the opioidergic hypothesis of alcoholism derives from the study of opioid antagonism on alcohol consumption. Opioid antagonists reliably decrease alcohol preference across a range of experimental conditions and across different animal species. Several placebo-controlled clinical trials in humans show efficacy of the opioid antagonists naltrexone (Volpicelli et al. 1992, O’Malley et al. 1992, Anton et al. 2006) and nalmefene (Mason et al. 1999) as adjuncts to the psychosocial treatment of alcoholism (discussed later).
Serotonin Neurotransmission

Serotonin (5-HT) also appears to play a role in modulating alcohol consumption (LeMarquand et al. 1994a). In rodents acute administration of alcohol is associated with an increase in the brain concentration of 5-HT, and central infusion of 5-HT enhances dopaminergic tone in the VTA (Brodie and Bunney 1996). In contrast, chronic administration of alcohol is associated with low central nervous system (CNS) concentrations of 5-HT. This reduction in serotonergic tone after chronic ethanol administration appears to be associated with behavioral disinhibition and impulsive aggression (Higley et al. 1996). Administration of serotonin reuptake inhibitors decreases alcohol consumption in rodents that show preference for alcohol (Gill and Amit 1989). Whether this phenomenon is due to a dampening of the reinforcing effects of alcohol or to a generalized reduction of consummatory behaviors is unclear (Gill and Amit 1989).

Data derived from humans also has suggested that disturbances in central serotonergic functioning may be involved in alcohol and drug dependence, particularly among substance-dependent patients diagnosed with a comorbid antisocial personality disorder. For example, in comparison to controls, antisocial alcoholics have lower basal CSF levels of 5-HIAA (Virkkunen et al. 1994).

GABAergic Neurotransmission

Behavioral responses to alcohol resemble the effects of pharmacological agents that predominantly affect GABAergic neurotransmission (i.e., benzodiazepines, barbiturates, and neurosteroids), suggesting a significant involvement of this system in the pharmacological effects of alcohol. Cross-tolerance with alcohol and the effectiveness of benzodiazepines and barbiturates in treating alcohol withdrawal symptoms also support this notion. Neurons that express GABA, receptors containing the alpha-1 subunit, such as cerebellar Purkinje neurons, appear to be sensitive to the effects of alcohol (Criswell et al. 1993). However, electrophysiologic responses to alcohol in neurons expressing GABA, receptors appear to be inconsistent (Harris 1999). It has been suggested that such inconsistencies may be due to the existence of alcohol-sensitive receptors and alcohol resistant receptors, determined by subunit composition and posttranslational processes (Mihic and Harris 1995). Strains of mice that differ in sleep sensitivity to alcohol (i.e., short sleep/long sleep [SS/LS] mice) show differential alcohol sensitivity of GABA, receptors. GABA, receptors in SS mice are resistant to alcohol, whereas GABA, receptors in LS mice are alcohol-sensitive (Allan and Harris 1986). Interestingly, individuals who are children of alcoholic fathers show increased resistance to induction of body sway and incoordination by alcohol administration. This finding suggests that people at risk for alcohol dependence experience decreased sensitivity to the effects of alcohol on the GABAergic system, and that this abnormality may be under genetic control (Schuckit 1994).

Glutamatergic Neurotransmission

Alcohol also affects the glutamatergic neurotransmitter system. Acute administration of alcohol antagonizes N-methyl-D-aspartate (NMDA) receptors (where glutamate acts as an agonist), whereas chronic administration increases these receptor sites (Chu et al. 1995). This latter finding reflects the fact that alcohol withdrawal symptoms and other neurotoxic effects of alcohol are mediated by glutamate. Furthermore, alcohol withdrawal appears to be associated with increased glutamate concentrations and decreased dopamine levels in the NAc (Dahchour et al. 1998). Findings concerning the efficacy of acamprosate (which exerts effects on the NMDA receptor) in the treatment of alcohol dependence suggest that this neurotransmitter system may have a major role in the disorder (Kranzler et al. 2000).

Cholinergic Neurotransmission

Studies in rodents have shown that the alcohol-induced dopamine release in the NAc can be antagonized by the central nicotinic receptor antagonist mecamylamine (Söderpalm et al. 2000). These findings suggest that the mesolimbic dopamine-activating and reinforcing effects of alcohol are both mediated in part by central nicotinic acetylcholine receptor activation. In healthy humans (Blomqvist et al. 2002), pharmacological manipulation of the nicotinic cholinergic receptor with mecamylamine reduces the stimulant effects of acute alcohol administration during the ascending limb of the blood alcohol curve. This finding suggests that blockade of nicotinic receptors may be a useful strategy in reducing alcohol consumption in alcoholics.

In summary, alcohol’s rewarding effects appear to be mediated by activation of the mesolimbic dopaminergic circuit particularly the VTA and the NAc. Alcohol reinforcement can also be explained by its effects on major neurotransmitter systems (i.e., opioidergic, serotonergic, GABAergic, glutamatergic and cholinergic) modulating the firing of dopaminergic neurons in the VTA and the release of dopamine in the NAc.

Assessment and Differential Diagnosis

Phenomenology and Variations in Presentation

Diagnostic criteria for alcohol use disorders in DSM-IV-TR (American Psychiatric Association 1994) are very similar to those employed in the International Classification of Diseases, Tenth Edition (ICD-10) (World Health Organization 1992), which in turn were based upon the alcohol dependence syndrome (ADS) concept of Edwards and Gross (1976). ADS is a conception of alcoholism that includes biological, cognitive, and behavioral elements.

The DSM-IV-TR diagnosis of alcohol dependence is given when three or more of the seven criteria are present (see DSM-IV-TR for alcohol dependence). Because physiological dependence is associated with greater potential for acute medical problems (particularly acute alcohol withdrawal), the first criteria to be considered are tolerance and withdrawal. The remaining criteria reflect the behavioral and cognitive dimensions of ADS: (a) impaired control (i.e., alcohol is consumed in larger amounts or over a longer period of time than was intended; there is a persistent desire or unsuccessful efforts to cut down or control drinking; the individual continues to drink despite knowledge of a persistent or recurrent physical or psychological problem), and (b) increased salience of alcohol (i.e., a great deal of time spent drinking or recovering from its effects; important social, occupational, or recreational activities are given up or reduced due to drinking).
Alcohol Dependence

Alcohol Abuse

Once a diagnosis of alcohol dependence is given, a specification is made concerning course. Early remission is used if no criteria (full remission) or fewer than three symptoms (partial remission) of alcohol dependence are present for at least 1 month, but less than 12 months. Sustained remission is used if no symptoms (full remission) or fewer than three symptoms (partial remission) of alcohol dependence are present for at least 12 months. Finally, if the individual is in a setting in which he or she has no access to alcohol, the course specifier in a controlled environment is added.

Alcohol abuse is considered to be present only if the individual’s drinking pattern has never met criteria for alcohol dependence and he or she demonstrates a pattern of drinking that leads to clinically significant impairment or distress, as evidenced by one or more of the four criteria in DSM-IV-TR for alcohol abuse.

Clinical Vignettes 1 and 2 provide case histories that illustrate the clinical presentation of various alcohol use

DSM-IV-TR Criteria

Alcohol Dependence

A maladaptive pattern of drinking as manifested by three or more of the following during a 12-month period:

1. Tolerance, that is, either:
   a. a need for markedly more alcohol to achieve intoxication
   b. markedly diminished effect despite continued consumption of the same amount of alcohol

2. Withdrawal, that is, either:
   a. two or more signs or symptoms (autonomic hyperactivity, tremor, insomnia, nausea or vomiting, transient illusions or hallucinations, psychomotor agitation, anxiety, grand mal seizures) within several hours of stopping or reducing heavy, prolonged drinking
   b. consuming alcohol or a related substance (e.g., benzodiazepines) to relieve or avoid withdrawal symptoms

3. Alcohol is often consumed in larger amounts or over a longer period than was intended

4. There is a persistent desire to cut down or control drinking

5. A great deal of time is spent in drinking or recovering from drinking

6. Important social, occupational, or recreational activities are given up or reduced because of drinking

7. Drinking is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.

Clinical Vignette 1

Mr. B is a 40-year-old, married, African-American grocery store owner who presents in a hospital’s emergency department at 5 am complaining of nausea, followed by vomiting of bright red blood. He is accompanied by his 19-year-old daughter, who succeeded in convincing her father to go to the hospital, rather than to work. Mr. B had no history of hospitalizations. He denied recent medical or psychiatric problems, saying he had not been to a doctor’s office for more than 15 years. Mr. B denied use of illicit or prescription drugs. Although he admitted drinking on a daily basis, he said he wasn’t an alcoholic. Upon specific questioning he revealed that he drank only beer, consuming in excess of 12 cans each day. Over the preceding 2 years he had been drinking only beer, but prior to that time he drank vodka on a daily basis, often in excess of a pint per day. He became increasingly alarmed, agitated, and tremulous as the interview progressed.

Family history provided by the patient’s daughter revealed that both of the patient’s parents were deceased. His father, who was alcoholic, had died from a myocardial infarction at age 42 years. His mother developed alcohol dependence after her husband’s death; she died of stomach cancer at age 55 years. Mr. B married at age 20 years and was divorced due to problems related to his drinking. There had been repeated marital conflicts over the 6 years prior to divorce, twice resulting in separations. The couple’s only child lived with her mother, but came to stay with her father when she learned that he was feeling ill.

In the emergency department, Mr. B was kept nothing by mouth (nil per os (npo)) and intravenous fluids were begun for hydration. Suction through a nasogastric tube produced 5 cc of dark, clotted blood. Emergency endoscopy showed inflamed, hemorrhagic gastric mucosa, with no active bleeding. There were no indications of esophageal varices, Mallory–Weiss tears, or other lesions. Prior to endoscopy the patient received lorazepam 2 mg IV, which dramatically reduced his agitation. He was then admitted to the medical service. The next day he agreed to be seen in consultation by a psychiatrist.

(continues)
Clinical Vignette 1 continued

During the interview with the psychiatrist, Mr. B admitted that he had previously come to the hospital with many of the same symptoms, although he had not previously vomited blood. Each time he had been treated with drugs that helped him calm down. He acknowledged that he had been told his symptoms resulted from heavy drinking, but he denied drinking “any more than most people.” Two years earlier he had switched from vodka to beer and had limited his intake to 6 beers per day in an effort to avoid the gastrointestinal problems. Although he had felt some nervousness and malaise at that time, his abdominal pain and nausea gradually improved. Subsequently, his beer consumption gradually increased and during the preceding 3 months the gastrointestinal symptoms reappeared.

The patient first consumed alcohol at age 14. He began regular drinking at age 18 years, drinking about a 6-pack of beer, 2–3 times per week after work or on weekends. At age 26 years he started his own business. The pressures of owning a business, combined with the freedom it permitted, led him to drink daily. As his consumption increased he found that drinking beer at work was too conspicuous, so he began drinking vodka, which he could do surreptitiously. As his business gradually floundered, he became increasingly irritable both at work and at home. Mr. B began arguing regularly with his wife, who complained about his drinking. Eventually, his wife and daughter moved to a house in a neighboring town.

The patient denied ever having experienced a seizure, but acknowledged multiple blackouts following particularly heavy drinking. Over the preceding year he had begun drinking beer early in the day to steady his hands. Toward the end of the interview, Mr. B stated that recently he had begun to think that what people had been telling him about his drinking was true. He exclaimed loudly, “I’ve had enough. What can I do about this? I’m willing to try anything now.” Upon resolution of his gastric hemorrhage and alcohol withdrawal symptoms, Mr. B was referred to a partial hospitalization program for rehabilitation.

Final DSM-IV-TR Diagnoses:

I. Alcohol Dependence, with physiological dependence; Alcohol Withdrawal, with perceptual disturbances
II. None
III. Upper Gastrointestinal Bleeding (Hemorrhagic Gastrosis) Macrocytic Anemia/Alcoholic Hepatitis

Clinical Vignette 2

Ms. C is a 28-year-old, white female, who separated from her husband 3 years ago. She is the mother of a 2-year-old boy and 6- and 12-year-old girls. The patient has been unemployed for 6 months, her most recent job having been as a barmaid. She was referred for substance abuse treatment from court, following arraignment on a charge of possession of narcotics. After 4 days in an inpatient rehabilitation program, she had stopped going to group meetings, spending most of her time alone in her room crying. She aroused particular concern in the treatment staff when she reported feeling that her life was no longer worth living. During the preceding year the patient had twice attempted suicide by taking an overdose of pills that she bought illicitly. On both occasions she was hospitalized briefly for observation.

When interviewed by the program psychiatrist, Ms. C complained that she missed her children too much to remain in treatment. With the help of her mother, she had been caring for her children, though the situation was being monitored by the child welfare agency after a charge of neglect had been filed by the children’s paternal grandmother. Ms. C acknowledged that completion of the rehabilitation program would probably help her to retain custody of her children, but she reported that she felt sad and discouraged, especially during the evening. She described recurrent periods of depressed mood since age 14 years, associated with initial and middle insomnia, low energy level and poor self-esteem. She had been suffering from these symptoms for approximately 2 months prior to admission. She also complained of decreased appetite and concentration, but denied recent weight loss, anhedonia, psychomotor retardation, or current suicidal ideation. When pressed concerning the onset of depressive symptoms, Ms. C indicated that they were generally worse when she used alcohol and cocaine heavily.

A substance use history revealed that Ms. C had begun smoking cigarettes when she was 11 years old, becoming a regular smoker at age 12. At the time of admission she was smoking about 1 pack of cigarettes daily. She also reported consuming alcohol and cannabis regularly for 13 years. She first drank alcohol at age 12, beginning regular drinking while a freshman in high school. Shortly thereafter she was introduced to marijuana, which she gradually increased to daily use, a practice that she continued until the time of admission. She began heavy drinking (up to 10 beers per day, 3–4 times per week) when she was 17 years old and a junior in high school. Since that time her drinking gradually increased, such that during the month prior to admission the patient reported drinking about a pint of spirits daily. She also reported a 5-year history of regular cocaine use, initially intranasally. Two years prior to admission she began smoking the drug and during the month prior to admission she reported smoking about $100 worth of cocaine 2–3 times per week. Although she had experimented with LSD, diazepam, and intranasal heroin, she denied regular or recent use of these drugs. She also denied intravenous drug use. One month earlier she was found to be HIV seronegative. The patient had never before been treated for substance abuse.

The patient acknowledged having a number of alcohol- and drug-related problems, especially the legal and child custody issues. Although her husband is also a substance abuser, she felt that her substance use had contributed to their breakup. While intoxicated they both became verbally and at times physically abusive toward one another. After not drinking for a day she often became turbulent and felt nauseated and weak. She denied any history of delirium tremens. While smoking cocaine she had on occasion become alarmed by a painful tightness in her chest, accompanied by palpitations and by transient paranoid ideation.

Family history revealed that both of the patient’s parents were alcoholic, her father having died of cirrhosis of the liver when Ms. C was 16 years old. The patient’s mother was in recovery, with nearly ten years of sobriety. The patient’s paternal grandfather, who had also been alcoholic, died before she was born. Ms. C is an only child. She reported that alcohol was readily available in her house and that sharing it with high school friends enhanced her popularity. She did well in school until 7th grade, when she began to find school boring. Ms. C was first arrested for shoplifting when she was 14 years old. She also began to have behavior problems...
at school around that time and was suspended for stealing money. At age 16 years, Ms. C left school due to her first pregnancy. She was subsequently arrested for shoplifting, disturbing the peace, and immediately prior to admission, for possession of cocaine.

Based upon the history and symptomatology at the time of evaluation, the psychiatrist decided to postpone pharmacotherapy pending longitudinal evaluation of her depressive symptoms. Daily monitoring of symptoms was implemented using the Beck Depression Inventory (BDI) (Beck et al. 1961). In addition, cognitive-behavioral therapy of depression was initiated by the addiction counselor who had been working with Ms. C. Over the subsequent week the patient’s depressive symptoms declined (with the BDI score decreasing from 25–19), but she continued to have difficulty participating in the treatment program. Fluoxetine 20 mg every morning was initiated and was well tolerated during the subsequent week. After completing the 21-day inpatient program, the patient was discharged to outpatient aftercare, where medication management was continued.

Final DSM-IV-TR Diagnoses

I. Alcohol Dependence, with physiological dependence; Cocaine Dependence, Cannabis Dependence; Major Depressive Disorder
II. Antisocial Personality Disorder
III. None

disorders and the application of DSM-IV-TR diagnostic criteria in evaluating alcoholic patients. In addition to alcohol abuse and dependence, there is another important group of alcohol-related disorders described in DSM-IV-TR as alcohol-induced disorders. These will be described briefly before returning to a discussion of assessment issues.

Alcohol Intoxication

A DSM-IV-TR diagnosis of alcohol intoxication is given when, shortly after alcohol consumption, there are maladaptive behaviors such as aggression or inappropriate sexual behavior, or there are psychological changes such as labile mood and impaired judgment. Clinical signs indicative of alcohol intoxication include slurred speech, lack of coordination, unsteady gait, nystagmus, impairment of attention and memory, and in the most severe cases, stupor and coma. Alcohol intoxication may also present with severe disturbances in consciousness and cognition (alcohol intoxication delirium), especially when large amounts of alcohol have been ingested or after alcoholic intoxication has been sustained for extended periods. Usually, this condition subsides shortly after alcohol intoxication ends. Physical and mental status examinations accompanied by analysis of blood and urine allow the clinician to rule out general medical conditions or psychiatric disorders mimicking this condition. In this regard, urine toxicology is a valuable tool in ruling out intoxication with benzodiazepines, barbiturates, or other sedatives that can present with a similar clinical picture. collateral information from relatives or friends confirming the ingestion of alcohol is also useful.

The blood alcohol level (BAL) is frequently used as a measure of alcohol intoxication, although this measure is less reliable in persons with a high degree of tolerance to alcohol. Alcohol is metabolized in the average adult at a rate of 1 oz or 7–10 g/hr. When this clearance rate is surpassed, signs of alcohol intoxication begin to appear. During the ascending limb of the BAL curve, euphoria, anxiolysis and mild deficits in coordination, attention, and cognition can be observed at levels between 0.01 and 0.10%. Marked deficits in coordination and psychomotor skills, decreased attention, ataxia, impaired judgment, slurred speech, and mood lability can be observed at a greater BAL. Severe intoxication, characterized by lack of coordination, incoherent thoughts, confusion, nausea, and vomiting can be observed at BALs between 0.20 and 0.30. However, at these levels some heavy drinking individuals who have developed tolerance to the effects of alcohol may not appear intoxicated and may perform well on psychomotor or cognitive tasks. Stupor and loss of consciousness often occur when the BAL is between 0.30 and 0.40. Beyond this level, coma, respiratory depression, and death are possible. It should also be noted that alcohol intoxication is often associated with toxicity and overdose with other drugs, particularly those with depressant effects on the CNS.

Alcohol Withdrawal

Alcohol withdrawal is a condition that follows a reduction in alcohol consumption or an abrupt cessation of drinking in alcohol-dependent individuals. In addition to significant distress, alcohol withdrawal is also associated with impairment of social, occupational, and other areas of functioning. Uncomplicated cases of alcohol withdrawal are characterized by signs and symptoms of autonomic hyperactivity, and may include increased heart rate, increased blood pressure, hyperthermia, diaphoresis, tremor, nausea, vomiting, insomnia, and anxiety. Onset of symptoms of uncomplicated alcohol withdrawal usually occurs between 4 and 12 hr following the last drink. Symptom severity tends to peak around the second day, usually subsiding by the fourth or fifth day of abstinence. After this period, less severe anxiety, insomnia, and autonomic symptoms may persist for a few weeks, with some individuals experiencing a protracted alcohol-withdrawal syndrome up to 5 or 6 months after cessation of drinking. A small but significant number of alcohol dependent individuals (10%) can experience complicated alcohol-withdrawal episodes. Alcohol withdrawal delirium (also known as delirium tremens) can occur in 5% of the cases, usually between 36 and 72 hr following alcohol cessation. In addition to signs of autonomic hyperactivity, this condition is characterized by illusions, auditory, visual, or tactile hallucinations, psychomotor agitation, fluctuating cloudiness of consciousness, and disorientation. Grand-mal seizures associated with alcohol-withdrawal occur in 3–5% of the cases, typically within the first 48 hr following reduction or cessation of drinking. In both instances of complicated alcohol withdrawal, lack or delay in instituting proper treatment is associated with an increased mortality rate. Prior history of delirium tremens and/or alcohol-withdrawal seizures, older age, poor nutritional status, comorbid medical conditions, and history of high tolerance to alcohol are predictors of increased severity of alcohol withdrawal.

Alcohol-Induced Persisting Amnestic Disorder (AIPAD)

Continuous heavy alcohol consumption can lead to several neurological deficits caused by thiamin deficiency. Among
them. AIPAD, also known as a Korsakoff’s psychosis, due to the fantastic confabulatory stories described by patients suffering this condition) is prominent. Profound deficits in anterograde memory and some deficits in retrograde memory characterize this condition. Patients cannot retain or learn new information and experience profound disorientation to time and place. The severity of anterograde memory deficits typically leads Korsakoff’s patients, who are unaware of their deficit, to reconstruct forgotten events by confabulating. Korsakoff’s amnestic disorder is usually preceded by several episodes of Wernicke’s encephalopathy, characterized by confusion, ataxia, nystagmus, and gaze palsies. When this condition subsides, the characteristic memory deficits of Korsakoff’s psychosis become prominent.

Cessation of drinking can lead to an improvement in memory with approximately 20% of the cases demonstrating complete recovery. However, in most cases memory deficits remain unchanged, and in some instances long-term care is needed despite sobriety.

**Alcohol-Induced Persisting Dementia**

Continuous heavy drinking is also associated with progressive and gradual development of multiple cognitive deficits characterized by memory impairment, apraxia, agnosia, or disturbances in executive functioning. These deficits cause serious impairment in social and occupational functioning and persist beyond the duration of alcohol intoxication and alcohol withdrawal. History, physical exam, and laboratory tests should be utilized to determine whether these deficits are etiologically related to the toxic effects of alcohol use. Other factors associated with this condition are poor nutritional status and vitamin deficiencies, as well as history of head trauma. It is believed that this condition is associated with the repeated occurrence of Wernicke’s encephalopathy. Atrophy of frontal lobes and increased ventricular size have been described in this condition. Continuous alcohol consumption exacerbates the dementia, whereas drinking cessation is associated with improvement and even recovery of cognitive deficits.

**Alcohol-Induced Mood Disorder (AIMD)**

AIMD, characterized by depressed mood and anhedonia, as well as elevated, expansive, or irritable mood, frequently develops as a consequence of heavy drinking. Onset of symptoms can occur during episodes of alcohol intoxication or withdrawal, and may resemble a primary major depressive, manic, hypomanic, or a mixed episode. In contrast to the dysphoria and lack of energy observed during episodes of alcohol withdrawal, severity, and duration of alcohol-induced mood symptoms are greater than what is usually expected, warranting independent attention by the clinician. Although mood disturbances are common among alcoholic patients entering treatment (80%), alcohol-induced mood symptoms tend to subside within 2−4 weeks following alcohol cessation. Evidence that the mood disturbances are not better explained by a primary mood disorder should be sought by the clinician. Evidence suggesting a primary mood disorder includes onset of mood symptoms preceding onset of alcohol abuse and persistence of mood symptoms after alcohol cessation or during extended periods of abstinence. Regardless of the primary or secondary nature of mood symptoms, given the high prevalence of suicide among alcoholics, clinicians should closely monitor the patient for emerging suicidal thoughts, implementing more intensive treatment (discussed later) if necessary.

**Alcohol-Induced Anxiety Disorder (AIAD)**

Although alcohol has anxiolytic properties at low doses, heavy alcohol consumption can induce prominent anxiety symptoms. Alcohol-induced anxiety (AIA) symptoms more commonly include generalized anxiety symptoms, panic attacks, and phobias. In order to establish this diagnosis, clinicians must rule out other general medical conditions or psychiatric disorders that can mimic this problem. AIA may develop during alcohol intoxication or withdrawal, but its severity and duration are typically worse than the anxiety normally observed during the course of these conditions. An onset of drinking preceding the anxiety syndrome, and improvement or remission of anxiety during periods of abstinence, suggest AIAD. Monitoring the course of these symptoms for several weeks after alcohol cessation can be useful in determining their nature. Usually, a substantial improvement of anxiety will be observed during this period, suggesting a direct relationship of anxiety to alcohol. In some cases, a full remission of symptoms is not observed until after 3−4 weeks of abstinence.

**Alcohol-Induced Psychotic Disorder**

This disorder is characterized by prominent hallucinations or delusions that are judged by the clinician to be due to the effects of alcohol. The psychotic symptoms usually occur within a month of an alcohol intoxication or withdrawal episode, and the patient is characteristically fully alert and oriented, lacking insight that these symptoms are alcohol-induced. Although onset of psychotic symptoms can occur during or shortly after alcohol intoxication, delirium or alcohol withdrawal delirium, alcohol-induced hallucinations, and/or delusions do not occur exclusively during the course of these conditions. Evidence that hallucinations and delusions are not part of a primary psychotic disorder include: atypical or late age of onset of psychotic symptoms, onset of alcohol drinking preceding the onset of psychiatric symptoms, and remission of psychotic episodes during extended periods of abstinence. Usually, alcohol-induced psychotic symptoms tend to subside within a few weeks of abstinence, although in a subset of patients psychotic symptoms can become chronic, requiring long-term treatment with antipsychotic medication. In these cases clinicians are obligated to consider a schizophrenic or a delusional disorder as part of the differential diagnosis.

**Alcohol-Induced Sleep Disorder (AISD)**

Heavy alcohol consumption can be associated with a prominent disturbance of sleep. At intoxicating BALs, especially when blood alcohol levels are declining, sedation and sleepiness can be observed. Alcohol intoxication induces an increase in nonrapid eye movement (NREM) sleep, whereas rapid eye movement (REM) sleep density decreases. Subsequently, there is an increase in wakefulness, restless sleep, and vivid dreams or nightmares related to a reduction in NREM sleep and a rebound in REM sleep density. During alcohol withdrawal, sleep is fragmented and discontinuous with an increase in REM sleep. After withdrawal, patients
frequently complain of sleep difficulties and may experience superficial and fragmented sleep for months or years.

In contrast to the primary sleep disorders (PSD), AISD is characterized by an onset of drinking preceding the sleep disturbance and by remission of symptoms during the course of sustained abstinence. AISD can occur during the course of a typical alcohol intoxication or alcohol withdrawal episode. However, duration and severity of the sleep disturbances exceed those typically observed during these conditions. Given that protracted alcohol-withdrawal symptoms are frequent among abstinent alcoholics, onset of AISD can occur up to 4 weeks after initiation of alcohol abstinence. History of a previous PSD and/or persistence of sleep disturbances for more than 4 weeks following intoxication or acute withdrawal are highly suggestive of a PSD. Differential diagnosis is complicated by the fact that heavy alcohol consumption can co-occur and exacerbate other psychiatric disorders that present with sleep disturbances (e.g., mood disorders, anxiety). Alcohol consumption can also intensify other sleep problems such as narcolepsy or breathing-related sleep disorders.

Alcohol-Induced Sexual Dysfunction
Although small doses of alcohol in healthy individuals appear to enhance sexual receptivity in women and facilitate arousal to erotic stimuli in men, continuous and/or heavy drinking may cause significant sexual impairment. Alcohol-induced sexual dysfunction is characterized by impaired desire, impaired arousal, and impaired orgasm, or sexual pain. It is also associated with marked distress or interpersonal conflicts. Onset of these impairments usually occurs during alcohol intoxication but duration of symptoms exceeds the uncomplicated course of alcohol intoxication. Symptoms usually subside after 3–4 weeks of alcohol abstinence. Persistence of symptoms beyond this time may suggest a primary sexual dysfunction or a sexual dysfunction due to the medical complications of alcoholism (e.g., neuropathy, alcoholic-liver disease). Onset of a recurrent sexual dysfunction preceding the onset of alcohol abuse also suggests a primary disorder. Use of other substances, particularly those prescribed for the treatment of alcohol withdrawal such as benzodiazepines or barbiturates, should be ruled out as a cause of the sexual dysfunction.

Assessment of Alcohol Use Disorders
Comprehensive assessment provides the basis for an individualized plan of treatment. Depending upon the severity of alcohol dependence, the nature of comorbid medical and psychiatric pathology, the presence of social supports, and evidence of previous response to treatment, decisions can be made concerning the most appropriate intensity, setting, and modality of treatment.

Although denial of alcohol-related problems is legendary among alcoholics, there is substantial evidence that a valid alcohol history can be obtained, given adequate assessment procedures and the right conditions (Babor et al. 1990). A complete alcohol history should include specific questions concerning average alcohol consumption, maximal consumption per drinking occasion, frequency of heavy drinking occasions, and drinking-related social problems (e.g., objections raised by family members, friends, or people at work), legal problems (including arrests or near-arrests for driving while intoxicated [DWI]), psychiatric symptoms (e.g., precipitation or exacerbation of mood or anxiety symptoms), and alcohol-related medical problems (e.g., alcoholic gastritis or pancreatitis).

It is crucial that questions concerning alcohol consumption and related problems be asked nonjudgmentally in order to enhance the likelihood of accurate reporting. The optimal approach to history-taking begins with reassuring the patient that information provided will be kept confidential. The interviewer should first ask questions that are least likely to make the patient defensive (e.g., a review of systems or psychiatric symptoms, without relating these to alcohol use), and begin questions with how, rather than with why, to reduce the appearance of being judgmental (Schottenfeld 1994).

Screening
Systematic clinical assessment often begins with routine screening to identify active cases, as well as persons at risk. During the past 25 years, a number of self-report screening tests have been developed to identify alcoholics as well as persons at risk of alcohol problems. Perhaps the most widely used alcohol screening test is the CAGE Test (Ewing 1984), which contains only four questions: (1) Have you ever felt you ought to cut (the “C” in CAGE) down on your drinking? (2) Have people Annoyed (A) you by criticizing your drinking? (3) Have you ever felt bad or Guilty (G) about your drinking? (4) Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover that is, an Eye opener (E)? Reliability and validity studies of this test have been conducted in diverse samples (e.g., psychiatric inpatients, ambulatory medical patients, prenatal clinics), with generally acceptable levels of sensitivity (Babor and Kadden 1985). There are several variants on the CAGE. For example, the TWEAK (Russell et al. 1991) contains slight modifications of the items (Tolerance, Worried, Eye-opener, Amnesia, Cutdown) that are geared toward pregnant women.

The Alcohol Use Disorders Identification Test (AUDIT) (Saunders et al. 1993, Babor and Higgins-Biddle 2001a), a 10-item screening instrument, may be used as the first step in a comprehensive and sequential alcohol use history. The AUDIT (Table 54–2) covers the domains of alcohol consumption, alcohol dependence, and alcohol-related consequences. It has been shown to be sensitive and specific in discriminating alcoholics from nonalcoholics, and is superior to other tests in identifying hazardous drinkers, that is, those heavy drinkers who have not yet experienced serious harm from their drinking. The AUDIT total score increases with the severity of alcohol dependence and related problems, and can be used as part of a comprehensive approach to early identification and patient placement (Babor and Higgins-Biddle 2001a, 2001b). Because the misuse of both prescribed and illicit drugs is common among alcoholics, screening should also include other psychoactive substances, including tobacco products.

Psychiatric History and Examination
Diagnostic assessment in specialized treatment facilities, such as detoxification centers, residential programs, partial hospital programs, and outpatient clinics, should be
conducted with a standard interview schedule. If it is not possible to use a complete psychiatric interview, such as the Composite International Diagnostic Interview (CIDI) (Robins et al. 1989) or the Structured Clinical Interview for DSM (SCID) (First et al. 1996), then the alcohol sections of these interviews should be used. Given the lack of reliability in unstructured clinical diagnosis, it is imperative that programs specializing in the treatment of alcohol dependence use a structured interview to conduct and report their diagnostic evaluations.

An important purpose of clinical assessment is to obtain an estimate of illness severity. The number of DSM symptoms obtained using a structured interview or the total score on the AUDIT screening test can serve this purpose. The Composite Score from the Drug and Alcohol Severity Index (ASI) (McLellan et al. 1992) is another useful measure of severity.

Assessment of psychological function should focus on measures of depression, anxiety, and more global psychological distress. Instruments that are generally reliable, valid, and acceptable in a variety of health care settings include the Beck Depression Inventory (Beck et al. 1961) and the Symptom Checklist-90-Revised (Derogatis 1977). One subscale of the ASI assesses overall psychiatric severity, including number of inpatient and outpatient treatment episodes, medication status, and lifetime and current symptomatology (McLellan et al. 1992).

There has been considerable attention devoted to the role of motivation and patient readiness to change, as critical ingredients in treatment planning for alcoholics. The University of Rhode Island Change Assessment Scale (URICA) is a 32-item questionnaire designed to measure the stages of change across diverse problem behaviors (Prochaska and DiClemente 1992). The URICA score profiles have been used to predict treatment response in research on addictive behaviors such as smoking and alcoholism. The readiness to change questionnaire (RCQ) (Rollnick et al. 1992) is a shorter instrument developed for the same purpose.

### Relevant Physical Examination and Laboratory Findings

Medical illness is a common consequence of heavy drinking even in the absence of physical dependence. Early in the course of alcohol use disorders individuals may show no physical or laboratory abnormalities. But as drinking progresses, it is widely manifested throughout most organ systems. A thorough physical examination is indicated if, in the history, there is evidence of medical problems. The physical examination provides essential information about the presence and extent of end-organ damage, and should be focused on the systems most vulnerable to developing alcohol-related pathology: the cardiovascular system, the gastrointestinal system, and the central and peripheral nervous systems. The physician should also be alert to other acute alcohol-related signs, including alcohol withdrawal or delirium, intoxication or withdrawal from other drugs, and the acute presentation of psychiatric symptomatology. Other systemic or nonspecific health problems associated with alcohol dependence include malnutrition, muscle wasting, neuritis, specific vitamin deficiencies, infectious diseases (such as tuberculosis, dermatitis, pediculosis, and hepatitis), and trauma secondary to fights and accidents (Arif and Westermeyer 1988) (Table 54–3).

A variety of laboratory tests can be helpful in assessing the effects of alcohol consumption. Patients experiencing alcohol use disorders are typically reluctant to seek help...

or tend to underreport the frequency and intensity of their drinking. Diagnostic laboratory markers can help to detect individuals who deny or minimize their alcohol consumption. Laboratory testing can also help to resolve diagnostic dilemmas among patients whose self-report information and physical findings are inconclusive (Allen and Litten 2001).

Laboratory testing can also assist the clinician in providing objective, nonjudgmental feedback to alcoholic patients on the negative physical consequences of excessive drinking. Laboratory determinations should be repeated biweekly at the initial phase of treatment, and monthly during the aftercare. Results should be graphically presented to the patient in an easy-to-comprehend format with reference to normal values. This allows the patient to appreciate the decline and eventual stabilization of laboratory indexes, thereby enhancing motivation to maintain sobriety. Laboratory tests can also help to detect relapse to the extent they are sensitive to heavy drinking. Early identification of relapse can prevent the reinstatement of alcohol dependence. It can diminish adverse consequences of heavy drinking by promoting modifications to the original treatment plan and by prompting more aggressive therapeutic interventions.

Several laboratory tests, particularly those related to hepatic function (e.g., serum transaminases, bilirubin, prothrombin time, and partial thromboplastin time) have been commonly used by clinicians. Other laboratory tests (e.g., gamma-glutamyl transpeptidase (GGTP), carbohydrate-deficient transferrin (CDT), mean corpuscular volume (MCV) of erythrocytes) can be used as objective indicators of heavy drinking (Peterson 2004). Elevation in GGTP occurs in approximately three-fourths of alcoholics before there is clinical evidence of liver disease. It is considered to be one of the earliest indications of heavy alcohol consumption and is widely available clinically (Holt et al. 1981). GGTP levels usually return to normal limits after 4–5 weeks of abstinence (Salaspuro 1986). As with GGTP, elevations of the transaminases serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) are common in other liver diseases. However, elevations in the transaminases are less sensitive indicators of heavy drinking, with SGOT being elevated in 32–77% of alcoholics, while elevations in SGPT have been observed in 50% of alcoholics (Holt et al. 1981). In contrast to the use of absolute values of SGPT and SGOT, the ratio of SGPT to SGOT may provide a more accurate indicator of heavy drinking. A ratio greater than 2 is more likely to be related to heavy alcohol consumption whereas a ratio below 1 would suggest a different etiology (Sharpe et al. 1996). Elevation of MCV, which has also been associated with folate deficiency, is more prominent in alcoholics, especially among those who are smokers. Though MCV can assist clinicians in identifying patients who are drinking excessively, particularly when this marker is used in combination with GGTP (or CDT), this is not an efficient indicator of relapse because of the 2–4-month period of abstinence that is needed for its normalization (Irwin et al. 1988).

CDT is more specific than most routine laboratory tests for the identification of heavy alcohol consumption (Peterson 2004). In contrast to GGTP, CDT elevations are associated with few conditions other than heavy drinking (Litten et al. 1995, Murawaki et al. 1997). Whenever possible, CDT and GGTP should be used together, with a positive case defined by elevated scores in either test. This approach increases the likelihood of identifying individuals experiencing alcohol use disorders (Allen and Litten 2001). CDT appears to detect relapse to heavy drinking among patients in alcohol treatment more accurately than other laboratory tests (Litten et al. 1995, Allen and Litten 2001).

In a clinical setting where laboratory results are generally not immediately available, the alcohol breath test, which measures the amount of alcohol in expired air (providing an estimate of venous ethanol concentration), is valuable. Although its accuracy depends on the patient’s cooperation (which in an intoxicated patient is often problematic), the alcohol breath test can be a reliable and inexpensive method for assessing recent alcohol consumption. Venous blood levels should be obtained if dangerously high levels of intoxication are suspected, when a patient is comatose, or for medical–legal purposes. A BAL greater than 150 mg/dl in a patient showing no signs of intoxication (i.e., no dysarthria, motor incoordination, gait ataxia, nystagmus, or impaired attention) can be interpreted to reflect physiological tolerance (DSM-IV-TR) (American Psychiatric Association 1994, Holt et al. 1981). In nontolerant individuals, a BAL in excess of 400 mg/dl can result in death, and 300 mg/dl indicates a need for emergency care.

Another laboratory evaluation that is indicated in alcoholics is a urine toxicology screen. To identify drug use that the patient may not admit or recognize, including pre-scription drug medications, the screen should include opiates, cocaine, cannabis, and benzodiazepines. Routine urinalysis, blood chemistry, hepatitis profile, complete blood count, and serologic test for syphilis and (for the female patient) serum testing for pregnancy should also be obtained.

Gender and Developmental Presentations

There are substantial differences in the prevalence of alcoholism among different gender, age, and racial/cultural groups. Unfortunately, the high prevalence among young adult and middle-aged males often leads to inadequate consideration of the possibility that women and the elderly may drink excessively.

Women

Women are more likely to abstain from alcohol, and if they do drink, they are more likely to consume less alcohol than men. Nevertheless, in comparison to men, problem drinking among women is more likely to be associated with negative mood states, particularly depression, anxiety, and somatic symptoms (Lesieur and Blume 1993). Alcoholic women
identify negative emotions and interpersonal conflicts as antecedents of a relapse to drinking more frequently than men (Annis and Graham 1995) and substance-dependent women more frequently report depressive and anxiety symptoms as motivators for treatment. These reports are consistent with epidemiological and clinical studies which show that women who are diagnosed with alcohol or drug dependence experience higher rates of mood and anxiety disorders than their male counterparts (Helzer et al. 1987). Furthermore, it is more common among women that mood and anxiety disorders precede the onset of substance use and dependence (Kessler et al. 1996). Alcoholic women have a negative profile of situations surrounding their alcohol use, characterized by solitary drinking and greater severity of alcohol dependence, whereas alcoholic men tend to have a positive profile, characterized by social drinking and drinking in the context of positive emotions (Annis and Graham 1995). Studies comparing male and female alcoholics (Parrella and Filstead 1988) have found that women are significantly older than men when a variety of alcohol-related milestones occur, including regular drunkenness, loss of control over drinking, first drinking problems, drinking to relieve withdrawal symptoms, first attempt to stop drinking, and realization that alcohol use is a problem. These studies have also found that women exhibit more rapid progression than men between the time of first regular intoxication and first treatment (Randall et al. 1999).

Despite drinking for fewer years at lower levels, women have an increased sensitivity to toxic effects of alcohol on body organs (Nixon 1993). Alcoholic women are more likely to develop liver damage and, in general, alcoholic liver diseases tend to progress faster among women than men (Becker et al. 1996). The five-year mortality rate among alcoholic women is almost twice the mortality rate of alcoholic men. Alcoholic women appear to be more susceptible to alcohol-induced brain damage, evidenced by greater widening of the cerebral sulci and fissures in CT scans of the brain (Jacobson 1986), as well as poorer performance in cognitive testing (Nixon 1993). The concept of “telescoping” has been used to describe the course of symptom progression observed among women who, despite beginning heavy drinking later than men, experience alcohol-related problems and seek treatment sooner than men (Piazza et al. 1989).

Since alcohol is distributed in the aqueous phase, greater body fat composition among women reduces the volume of distribution. This, combined with smaller average body mass, translates into higher BALs for women in response to a specified level of alcohol consumption (Goldstein 1992). In addition, less first-pass metabolism due to less gastric oxidation of ethanol may also contribute to the higher blood levels obtained by women following an equivalent dose of ethanol (Frezza et al. 1990). Compared with men, women with alcohol problems are also at greater risk of comorbid drug abuse/dependence (Lex 1992). Perhaps, as a consequence of these differences, women alcoholics who seek treatment do so earlier in the course of the disorder than do men (Nixon 1993).

Because heavy drinking among women is most prevalent during the childbearing years, it has important public health implications for prenatal alcohol exposure and possible fetal alcohol spectrum disorders (FASDs, Wattendorf and Muenke 2005). A variety of adverse outcomes have been related to heavy drinking in pregnant women, although the minimum amount of alcohol and the pattern of consumption necessary to produce such effects are not known. Heavy drinking in pregnant women may produce malnutrition in both the mother and the fetus, as well as spontaneous abortion, preterm delivery, and intrauterine growth retardation (Hannigan et al. 1992). FASDs are estimated to occur in as many as 1 in 100 live births (Finnegan and Kandall 1992). The most severe manifestation of FASD is fetal alcohol syndrome (FAS), a constellation of morphological and developmental defects resulting from high-dose prenatal alcohol exposure. FAS is estimated to occur in 1 in 1000 to 1 in 300 live births (Finnegan and Kandall 1992). Prenatal or postnatal growth retardation, CNS involvement, and characteristic facial dysmorphology are necessary for a diagnosis of FAS (Sokol and Clarren 1989).

Since FASDs can be avoided, the evaluation of pregnant patients should routinely include questions about alcohol and other substance use. Routine screening with an instrument such as the AUDIT, or the Tolerance-Annoyance, -Cut down, and -Eye opener (T-ACE test), supplemented by questions concerning drug use, may also be useful with pregnant women. The T-ACE, as described in Table 54.4, is the first screening test developed for pregnant women (Sokol et al. 1989). The T-ACE is used to screen for pregnancy risk drinking, defined here as the consumption of 1 ounce or more of alcohol per day while pregnant. Those pregnant women who are identified as high risk drinkers or drug users should be provided with a brief intervention, appropriate clinical evaluation and referral, if necessary (Finnegan and Kandall 1992).

*According to Sokol et al. (1989), scores are calculated as follows: An answer of “more than two drinks” to question T is considered a positive response and counts for 2 points. Affirmative answers to questions A, C, and E are counted as 1 point for each. A total score of 2 or more points on the T-ACE indicates a positive screen for pregnancy risk drinking.

Adolescents

There are a number of features that distinguish adolescents with alcohol abuse/dependence from adult alcoholics. As might be expected, adolescents have comparatively short histories of heavy drinking. A corollary to this is the rarity of physiological dependence on alcohol and alcohol-related medical complications among adolescents. Diagnosis of alcohol dependence is further complicated by the possible confusion of hangover symptoms with withdrawal phenomena, and the rapid development of alcohol tolerance (Winters 2001). Nonetheless, the use of alcohol and other psychoactive drugs contributes in important ways to morbidity and mortality in adolescents, the leading causes of which are motor vehicle accidents, homicide, and suicide. The values and behavior of the peer group are important
elements in the evaluation of alcohol use and abuse in the adolescent. The evaluation of adolescents with an alcohol disorder must also take into account other prominent developmental issues, including internal and externalizing disorders, as well as the conflict inherent in asserting one’s independence from the family.

A number of instruments have been developed for the assessment of substance use symptoms and disorders in adolescents (Winters 2001). As is generally true in dealing with adolescents, given their economic and emotional dependence, whenever possible a thorough family evaluation is important for understanding the adolescent’s substance use and related problems.

The Elderly

Although heavy drinking is less prevalent in the elderly, it is nonetheless an important source of morbidity in this group. Elderly alcoholics suffer from more chronic medical problems and poorer psychosocial functioning than elderly nonalcoholics (Finlayson et al. 1988). The increased use of prescription medications in the elderly increases the potential for adverse pharmacokinetic interactions with alcohol. In addition, decreased cognitive functioning associated with heavy alcohol use can increase medication errors and non-compliance in this group (Ofman 1992).

The manifestations of alcohol dependence in the elderly are often more subtle and nonspecific than those observed in younger individuals (Ofman 1992, Graham 1986). Because self-reported alcohol consumption may be particularly unreliable in the elderly, other sources of information such as family and neighbors should be used to identify heavy drinkers (Graham 1986). The following areas should be systematically evaluated in the elderly when heavy drinking has been identified: untreated medical illness, prescription drug abuse, psychiatric comorbidity, cognitive impairment, functional assessment, and need for social services (Ofman 1992).

Similar to the approach used with younger adults, alcohol dependence in the elderly has been classified by age of onset. It has been estimated that about two-thirds of elderly alcoholics began heavy drinking prior to age 60, while the remaining one-third began heavy drinking after the age of 60 (Atkinson and Kofoed 1982). Late-onset alcoholism appears to be more common among women and people of higher socioeconomic status and is less frequently associated with a family history of alcoholism (Ofman 1992). As might be expected, older alcoholics with early-onset alcoholism also have more alcohol-related medical and psychosocial problems and are more likely to require alcoholism treatment (Ofman 1992).

Epidemiology and Comorbidity

International Patterns of Drinking and Types of Alcohol Problems

Alcohol in beverage form is among the most widely used psychoactive drugs in the world. Because of its widespread distribution and the readiness with which it is consumed in a variety of settings, people do not generally think of beverage alcohol as a drug. Nonetheless, its complex pharmacologic actions, including a panoply of psychoactive effects, have led societies throughout the world to surround alcoholic beverages with a variety of rules and regulations governing their use (Babor et al. 2003). Despite these efforts at control, excessive drinking, with its adverse effects is widespread.

Patterns of drinking and the types of problems associated with alcohol misuse differ markedly throughout the world (Room et al. 2002). While the highest alcohol consumption rates are generally found among the industrialized countries of Europe and the North American continent, the lowest consumption rates are found in developing countries that are dominated by Islam, which proscribes the use of alcohol. The percentage of drinkers in adult populations ranges from a high of 86% in the North and Central European countries to less than 10% of adults in Islamic countries such as Pakistan and Iraq (Room et al. 2002). According to recent estimates from the World Health Organization’s (2007) Expert Committee, the evidence of alcohol’s impact on health through its intoxicating, dependence-producing, and toxic qualities is extensive. Alcohol is estimated to cause a net harm of 3.7% of all deaths, and 4.4% of the global burden of disease, as measured in Disability Adjusted Life Years lost (DALYs). Neuropsychiatric disorders, mainly made up of alcohol use disorders, account for the highest proportion of alcohol-attributable DALYs.

In the wine-producing Mediterranean countries (i.e., Spain, Portugal, Italy, France, and Greece), the pattern of drinking and the type of alcoholism have historically been associated with the consumption of wine as a dietary supplement, as well as for its effects as a social lubricant, medicine, and stimulant for manual workers. Wine is typically consumed in moderation by a large segment of the population, and it is used more for its social and presumed nutritional value than for its psychological effects. Drunkenness is uncommon, considering the high level of daily consumption, and there are few legal restrictions on the availability of alcoholic beverages. However, given their high levels of alcohol consumption, it is not surprising that the wine-producing countries of Europe lead the world in many indicators of alcohol-related chronic health problems (Babor et al. 2003).

In contrast to the preponderance of wine drinking in the Mediterranean region, the use of distilled spirits predominates in the northern periphery of Europe. In countries such as Norway, Sweden, Finland, Poland and Russia, there is a separation of drinking from dietary functions and the deliberate use of alcohol to produce intoxication. Heavy drinking is concentrated in a relatively small portion of the male population. As might be expected from this pattern of drinking, problems in spirits-drinking countries consist largely of alcohol-related accidents, public intoxication, and social disruption. In the predominantly beer-drinking countries of Germany, Austria, Belgium, the US, and the UK, per capita consumption tends to be intermediate between the wine-drinking and spirits-drinking countries. These countries are characterized by more diversified drinking customs.

World trends in alcohol consumption indicate that levels of alcohol use have been stable or slightly decreasing in Western Europe and the US since 1960. Alcohol consumption in the US, for instance, dropped from 2.8 gallons of ethanol per person in 1982 to 2.2 gallons per person in 2004 (Lakins et al. 2006). After a period of increased
Section VI • Disorders

consumption that peaked in the late 1970s and early 1980s, alcohol consumption in African countries has also been in decline. Conversely Asian countries such as China, South Korea, and Thailand have experienced steady increases in alcohol consumption since the late 1970s (Babor et al. 2003, Room et al. 2002).

Advances in the assessment of drinking behavior and its consequences have made it possible to estimate the prevalence of alcoholism in different cultural contexts (Helzer and Canino 1992). Cross-national studies employing structured diagnostic interviews have found lifetime prevalence rates of alcohol abuse/dependence that vary from as low as 0.45% (among Chinese in Shanghai) to a high of 23% (among US-born Mexican-Americans) (Helzer and Canino 1992). In addition to the overall differences in lifetime prevalence rates in different countries, the prevalence of alcohol dependence varies considerably within countries as a function of demographic characteristics, such as sex, age, geographic region and population density (Helzer and Canino 1992, Substance Abuse and Mental Health Services Administration 2001).

Patterns of Drinking and Types of Alcohol Problems in the US

Table 54–5 shows the prevalence rates of lifetime, past year, and past month drinking, including binge and heavy drinking, for different gender, age and racial/ethnic groups, as determined by the 2005 National Household Survey of Drug Use and Health (Substance Abuse and Mental Health Services Administration 2006). As shown in the table, the majority (87.8%) of the US population 18 and older has used alcohol in their lifetime, and more than half (55.9%) report current drinking. The highest rates of current use are among young adults aged 18–25 years, with males predominating. Non-Hispanic whites have the highest prevalence of drinking (91.4% lifetime use and 60.3% past month use), while Asians are least likely to drink (67.2% lifetime and 41.8% current). The prevalence of drinking is positively associated with education level; persons with less than a high school education are almost half as likely to report past month drinking as college graduates (36.7% compared to 69.4%).

Approximately one in four persons aged 18 years and older (24.1%) reported binge drinking (defined as five or more drinks per occasion) in the past month, and 7.1% reported heavy alcohol use (Table 54–5). Both binge and heavy drinking are more likely among men than women. Young adults aged 18–25 are twice as likely to binge drink and three times as likely to report heavy alcohol use compared to those 26 or older. Asians have the lowest levels of binge drinking and heavy alcohol use (13.9 and 2.2%, respectively), whereas Native Americans have the highest rates (36.2 and 12.8%, respectively).

Regarding the prevalence of alcohol disorders in the US, the most authoritative estimates derive from the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) conducted by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) (Grant et al. 2006). Based on face-to-face interviews with a national probability household sample of 43,093 adults 18 and older, the survey found that the past-year prevalence of DSM-IV-TR alcohol disorder was 8.5%, including 4.7% with alcohol abuse and 3.8% with alcohol dependence (Grant et al. 2006). In addition, the Substance Abuse and Mental Health Services Administration's (SAMHSA) collects data annually from approximately 70,000 persons aged 12 or older through the National Survey of Drug Use and Health (NSDUH). The 2005 NSDUH found the 1-year prevalence

*Low precision; no estimate reported.

Note: “Binge” Alcohol Use is defined as drinking five or more drinks on the same occasion on at least 1 day in the past 30 days. By “occasion” is meant at the same time or within a couple hours of each other. Heavy Alcohol Use is defined as drinking 5 or more drinks on the same occasion on each of 5 or more days in the past 30 days; all Heavy Alcohol Users are also “Binge” Alcohol Users.

of DSM-IV-TR alcohol abuse and dependence among the total population of persons 12 and older to be 7.7%, a prevalence rate that has remained statistically unchanged since 2002 (Substance Abuse and Mental Health Services Administration 2006). Differences in the rates of disorder across various studies have been attributed to differences in measurement procedures and sampling approaches (Regier et al. 1998).

The rates of alcohol use disorder vary by gender, age, race, ethnicity, socioeconomic status, and geographic location. The prevalence of alcohol disorder is consistently found to be higher among men than women, often at a ratio of two to one or greater (Grant et al. 2006, Kessler et al. 1997, Substance Abuse and Mental Health Services Administration 2006). Evidence suggests, however, that the gender differential has narrowed among more recent cohorts of young adults, in part due to an increased likelihood of early onset drinking among women and the subsequent emergence of drinking problems (Nelson et al. 1998). As shown in Table 54–6, the highest rates of alcohol abuse and dependence occur among young adults, with a gradual decline associated with increasing age. In the 2001–2002 NESARC, the prevalence rate for alcohol disorder was 16.2% among 18–29-year-old adults, dropping to 9.7% among those 30–44-year-old, 5.4% in the 45–64-year-old group, and 1.5% among those aged 65 years and older (Grant et al. 2006). Analyses of the NESARC data according to racial and ethnic background indicate that the highest prevalence rates of alcohol abuse and dependence occur among Native Americans (5.6 and 6.4%, respectively), while the lowest rates were found for Asians (2.1% for abuse and 2.4% for dependence). There is a negative association between education level and alcohol dependence (Kandel et al. 1997), and 1-year alcohol dependence risk is highest among the unemployed (Substance Abuse and Mental Health Services Administration 2006). Urban residence is associated with higher rates of alcohol dependence (Substance Abuse and Mental Health Services Administration 2000). Analyses of the 1999 NHSDA also show regional differences in the rates of alcohol dependence among the population aged 18 years and older, ranging from 3.4% in the Northeast and South, to 4% in the Midwest and 4.2% in the Western states (Substance Abuse and Mental Health Services Administration 2000).

Adverse consequences of drinking include a variety of social, legal, and medical problems (Babor et al. 1987). Overall, alcohol-related mortality in 1988 totaled 107,800 deaths, or about 5% of all deaths in the US, putting it among the top four causes of death (Stinson and DeBakey 1992). Of alcohol-related deaths, approximately 17% were directly attributable to alcohol, 38% resulted from diseases indirectly attributable to alcohol and 45% were attributable to alcohol-related traumatic injury (US Department of Health and Human Services 1994). Alcohol-related mortality declined during the last few decades of the 20th century. The age-adjusted mortality rate from liver cirrhosis in 1993 (7.9 deaths/100,000 persons) was almost half the 1970 rate (14.6 deaths/100,000) (Saadatmand et al. 1997), and alcohol-related automobile fatalities fell to a 2-decade low of 33.6% (Lane et al. 1997). Nonetheless, age-adjusted rates of liver cirrhosis in 1988 remained higher for males (43.4 deaths/100,000 population) than females (19.4 deaths/100,000 population) and for nonwhites (57.2 deaths/100,000 population) than whites (32 deaths/100,000 population) (Stinson and DeBakey 1992).

As noted previously in this chapter, alcohol-related morbidity is manifested in virtually all organ systems. The primary chronic health hazard associated with heavy drinking is cirrhosis of the liver, which in 1988 was the ninth leading cause of death in the US (U.S. Department of Health and Human Services 1994). Although the percentage of drivers in fatal crashes with BALs in excess of the legal limit has declined in recent years, alcohol intoxication remains a major contributor to this and other types of accidental injury, as well as to suicide and homicide (U.S. Department of Health and Human Services 2000). In addition, heavy drinking has been implicated in such health conditions as FASDs, esophageal cancer, chronic pancreatitis, nutritional deficiencies, cardiomyopathy, hypertension, and neurological problems (U.S. Department of Health and Human Services 2000). The social consequences of alcohol abuse and dependence are equally serious, with heavy drinking contributing to a variety of family, work, and legal problems. The economic impact of alcoholism is substantial. Alcohol abuse and dependence contribute to unemployment, reduced productivity in the workplace, and crime, as well as increased costs for health care (U.S. Department of Health and Human Services 2000). It has been estimated that the nonhealth related costs associated with alcohol abuse reached approximately $13 billion in 1992, owing in part to costs associated with crime committed while under the influence of alcohol (Martin 2001). In summary, the annual cost of heavy drinking and alcohol-related disorders in the US (both in dollars and in suffering) is enormous. Successful efforts to reduce the burden of illness attributable to alcohol could produce substantial

**Note:** Alcohol abuse and dependence are based on the definition found in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. (DSM-IV-TR).

Psychiatric Comorbidity in Individuals with an Alcohol Use Disorder

High rates of psychiatric disorders have been found in both clinical and community samples of alcohol-dependent individuals (Regier et al. 1990, Kessler et al. 1994, 1997, Ross 1995, Helzer and Pryzbeck 1988). These studies show a consistent association between alcohol abuse/dependence and a variety of other psychiatric symptoms and disorders. The Epidemiological Catchment Area (ECA) study, for example, revealed that 36.6% of those with a lifetime alcohol use disorder received at least one other psychiatric diagnosis, which is nearly double the rate for community respondents with no lifetime alcohol disorder (Regier et al. 1990). The evidence from the National Comorbidity Survey (NCS) study showed that co-occurring disorder is more likely with alcohol dependence than alcohol abuse (Kessler et al. 1997). Among individuals with one or more psychiatric disorders, 22.3% also had a lifetime alcohol disorder, substantially greater than the overall lifetime prevalence of alcohol abuse/dependence (13.5%). Women diagnosed with an alcohol disorder appear to be at greater risk for a comorbid psychiatric disorder. The NCS found that 72% of females with a lifetime alcohol abuse diagnosis had experienced one or more co-occurring psychiatric disorders, compared to 57% of men who had a lifetime history of alcohol abuse. While the prevalence of comorbid disorders was greater with alcohol dependence, the gender differential was smaller: 86% of women and 78% of men with lifetime alcohol dependence had had other lifetime DSM-III-R disorders (Kessler et al. 1997).

The most frequent co-occurring diagnoses are for other drug use disorders, conduct disorder, antisocial personality disorder, anxiety disorders, and affective disorders. The relative risks for different types of disorder vary somewhat by gender (Helzer and Pryzbeck 1988, Kessler et al. 1997). Among women, anxiety and affective disorders are the most common co-occurring disorders. Among men with a history of alcohol abuse or dependence, drug disorders and conduct disorder account for the largest proportion of comorbid cases.

Drug abuse/dependence is common among both men and women with an alcohol use disorder. In the NCS, slightly less than half of alcohol dependent respondents (41% of men and 47% of women) and approximately one-third of alcohol abusers had a history of a drug use disorder (Kessler et al. 1997). In the ECA study, 21.5% of individuals with a history of alcohol disorder also met criteria for a lifetime drug use disorder (odds ratio (OR) = 7.1) (Regier et al. 1990). Among individuals with a drug use disorder in the ECA study, 47.3% also had an alcohol disorder. The association was strongest for individuals with cocaine abuse/dependence, among whom 84.8% also had an alcohol use disorder (OR = 36.3). Other drug abuse/dependence diagnoses with an OR in excess of 10 included barbiturates, opiates, amphetaamines, and hallucinogens (Regier et al. 1990).

Problem drinkers have a significantly increased risk of the antisocial personality disorder (ASPD), compared to those in the population with no alcohol use disorder. Although ASPD was present in only 14.3% of individuals with an alcohol use disorder in the ECA study, this translated into an OR of 21 (Regier et al. 1990). Given that 73.6% of ECA respondents with ASPD also had a drinking pattern that met criteria for alcohol abuse/dependence, there is substantial overlap between the disorders, which is in part attributable to the overlap in diagnostic criteria (e.g., antisocial behavior that is manifest as a consequence of intoxication).

Evidence from multiple studies indicates that individuals with an alcohol use disorder experience a two to threefold increased risk of depressive disorders (Swendsen et al. 1998). The ECA study showed mood disorders to be present in 13.4% of those with an alcohol use disorder (OR = 1.9) (Regier et al. 1990). Conversely, 21.8% of individuals with a mood disorder also had an alcohol use disorder. Of the mood disorders, bipolar disorder is particularly common among individuals with an alcohol use disorder, with 5.1% having a form of bipolar disorder. Conversely, among individuals with bipolar disorder, 43.6% have a comorbid alcohol use disorder (OR = 5.1). Other mood disorders, although generally more common, show substantially lower odds ratios with alcohol use disorders. Specifically, major depressive disorder, which is present in 16.5% of individuals with an alcohol use disorder, has an odds ratio of only 1.3. Similarly, dysthmic disorder, although present in 20.9% of individuals with an alcohol use disorder, has an odds ratio of only 1.7. Among individuals with an alcohol use disorder, women were about four times as likely as men to receive a diagnosis of either bipolar disorder or major depressive disorder (Helzer and Pryzbeck 1988). There is also a sex differential with respect to the order of onset of diagnoses. In men, alcoholism is the antecedent diagnosis in 78% of cases of comorbid mood disorder, while for women major depressive disorder is the antecedent diagnosis in 66% of cases of comorbidity (Helzer and Pryzbeck 1988). The NCS study found a similar gender difference in the sequencing of comorbid affective disorders and alcohol use disorders (Kessler et al. 1997).

Anxiety disorders have also been found to be highly prevalent among individuals with an alcohol use disorder (Regier et al. 1990, Kessler et al. 1997, Swendsen et al. 1998). The ECA study found that 19.4% of those with alcohol abuse/dependence had a comorbid anxiety disorder (Regier et al. 1990). However, because these disorders are also highly prevalent in the general population, they have an odds ratio of only 1.5. Among individuals with an anxiety disorder, 17.9% have a comorbid alcohol use disorder. Of the anxiety disorders, panic disorder appears to have the strongest association with alcohol use disorder: 28.7% of individuals with that disorder also have an alcohol use disorder (OR = 2.6). Obsessive–compulsive disorder (OR = 2.1) is intermediate between panic disorder and phobias (OR = 1.4) (Regier et al. 1990). Among individuals with an alcohol use disorder, women were more than three times as likely as men to have panic disorder, and more than twice as likely to have phobia (Helzer and Pryzbeck 1988). Evidence suggests that the onset of social phobia occurs prior to the onset of alcohol use disorder, and that self-medication may play a role in the co-occurrence of the two disorders (Merikangas et al. 1998). A history of posttraumatic stress disorder (PTSD) has been found among 10.3% of men and 26.2% of women with a history of alcohol abuse. While the prevalence of comorbid psychiatric disorders is greater with alcohol dependence, the gender differential in the proportion of cases of comorbidity (Helzer and Pryzbeck 1988).
with alcohol dependence (Kessler et al. 1997). In the NCS study, the onset of an anxiety disorder appeared to precede the onset of an alcohol use disorder for women more than men (Kessler et al. 1997).

Among individuals with an alcohol use disorder, the prevalence of schizophrenia is 3.8%, which is almost three times the rate of that disorder in the general population (Regier et al. 1990). Conversely, among patients with schizophrenia, the prevalence of a comorbid alcohol use disorder is 33.7% (OR = 3.3). Considerable attention has been focused on the substantial problems encountered in treating patients with schizophrenia and comorbid alcohol and drug abuse/dependence (National Institute of Mental Health 1990).

Comorbidity influences treatment-seeking behavior. Although the majority of individuals with an alcohol use disorder do not seek treatment, comorbidity increases the likelihood of using both mental health and substance abuse treatment services (Wu et al. 1999). This was demonstrated by an analysis of the ECA data, which found that 55.0% of individuals with an alcohol use disorder seeking treatment in a mental health or substance abuse setting had a comorbid nonsubstance use disorder, compared with only 24.4% of individuals with an alcohol use disorder who had not sought treatment (Regier et al. 1990). Data from the ECA study also revealed that, even after controlling for the severity of alcohol use disorder, the number of comorbid nonsubstance diagnoses in individuals with an alcohol disorder is significantly correlated with the frequency with which they seek treatment for psychiatric and medical problems (Helzer and Pryzbeck 1988).

Given these findings from general population surveys, it is not surprising that in clinical settings individuals with an alcohol use disorder also have a high prevalence of comorbid psychiatric disorders. Consistent with the patterns observed in the general population, the most common comorbid disorders are major depressive disorder, ASPD, drug dependence, and anxiety disorders (Hesselbrock et al. 1985, Ross et al. 1988). However, the prevalence of comorbid disorders observed in clinical samples appears to vary as a consequence of a number of factors, including the method of assessment, the sample studied, and the recency of heavy drinking (Grande et al. 1984, Kranzler and Liebowitz 1988). Given the overlap in the diagnostic criteria for alcohol dependence and ASPD, and the effects of chronic heavy drinking on mood and anxiety symptoms, care must be taken to differentiate transient, alcohol-related signs and symptoms from persistent features.

Powell et al. (1982) used a structured diagnostic interview to examine the lifetime prevalence of comorbid DSM-III-R disorders among 565 male inpatient veterans being treated for alcohol dependence. They found that 63% of patients had psychiatric symptoms that met criteria for a psychiatric diagnosis in addition to alcohol dependence. The most common comorbid diagnosis was depression (42% of all patients), followed by mania (20%) and ASPD (20%). Comorbid drug abuse was present in 12% of patients, with panic attacks, phobic disorder, and obsessive–compulsive disorder each diagnosed in approximately 10% of patients. A comorbid diagnosis of schizophrenia was present in 4% of patients. The onset of comorbid disorders, with the exception of depression and obsessive–compulsive disorder occurred prior to the onset of alcoholism.

Hesselbrock et al. (1985) evaluated a group of 321 individuals with an alcohol use disorder recruited from three different inpatient settings. These investigators found that 75% of men and 80% of women received one or more lifetime diagnoses in addition to alcohol abuse/dependence. For the entire group, drug abuse was the most prevalent lifetime diagnosis (45%), followed by ASPD (41%), major depressive disorder (38%), phobia (27%), obsessive–compulsive disorder (12%), panic disorder (10%), mania (4%), and schizophrenia (2%). Gender differences were also evident, with the most common comorbid diagnosis being ASPD among men (49%) and depression among women (52%). With respect to disorders other than ASPD, the onset of most comorbid disorders in women preceded the onset of alcohol abuse, while among men most comorbid disorders followed the onset of alcohol abuse.

Ross et al. (1988) evaluated the prevalence of comorbid psychiatric disorders in a sample of 501 patients seeking treatment. Among patients with a current alcohol use disorder ($n = 370$), 25% had comorbid drug abuse/dependence. Patients who received both alcohol and drug abuse/dependence diagnoses had a higher prevalence of other lifetime psychiatric diagnoses (95%) than those with only an alcohol diagnosis (78%). The most common disorder among patients with combined alcohol and drug abuse/dependence was ASPD (79%), followed by psychosexual dysfunctions (48%), major depressive disorder (36%), phobias (36%), dysthymic disorder (23%), obsessive–compulsive disorder (18%), panic disorder (17%), pathological gambling (14%), schizophrenia (11%), and mania (3%). A similar distribution was evident among patients with no comorbid drug diagnosis, although in each case the prevalence was lower. With respect to the order of onset, alcohol abuse/dependence most commonly occurred after the onset of ASPD, schizophrenia, phobias, and panic disorder. Onset of the other comorbid disorders relative to alcohol abuse was more variable.

In summary, both community and clinical studies underscore the importance of ASPD and drug abuse/dependence as comorbid diagnoses in individuals with an alcohol disorder. The odds ratios obtained for these disorders in community studies indicate that these associations are elevated not only as a function of greater treatment-seeking behavior in affected individuals, but also because of potential commonalities in the etiology and development of alcohol abuse/dependence. That is, genetic and/or psychosocial risk factors for the development of ASPD are likely to overlap with factors that increase risk for alcohol and drug use disorders. Similarly, the risk factors for alcohol and drug use disorders may overlap with those for schizophrenia and bipolar disorder. In contrast, although anxiety disorders and depression are highly prevalent in clinical samples of alcohol-dependent individuals, their association with alcohol dependence appears largely due to chance, since these disorders are also highly prevalent in the general population.

Given a high rate of psychiatric comorbidity, it is axiomatic that a careful psychiatric assessment should be conducted in patients being seen for alcohol treatment, and that alcohol use and associated problems be evaluated in patients seen primarily for other psychiatric conditions. Because the presence of comorbid disorders may have important implications for the development of alcoholism.
and its prognosis, the assessment of comorbid psychopathology is an essential element in the clinical evaluation. When comorbid diagnoses are present, an effort should be made to ascertain the order of onset of each disorder since treatment and prognosis may follow from such information (Schuckit 1985).

**Course and Natural History**

Schuckit et al. (1993) found that the symptoms of alcohol dependence appear in the following sequence in a sample of male veteran alcoholics: (1) heavy drinking during the late twenties; (2) interference with functioning in multiple life areas during their early thirties; (3) loss of control, followed by an intensification of social and work-related problems, and onset of medical consequences in the mid-to late thirties; and (4) severe long-term consequences by the late thirties and early forties. This relatively predictable order of progression is consistent with previous studies. However, as mentioned above, women appear to experience many of these milestones at a later age than men (Parrella and Filstead 1988, Piazza et al. 1989).

The study by Schuckit et al. (1993) showed no effect of onset age, family history of alcoholism, or comorbid psychiatric diagnoses on the order of symptom appearance. However, other features defining the course of alcoholism, particularly the response to treatment, vary as a function of patient-related variables, including age of onset, severity of alcohol dependence, and comorbid psychiatric disorders. There is consistent evidence that early age of onset is a predictor of greater severity of alcoholism and a poorer response to treatment (Bohn and Meyer 1994, Babor et al. 1992). Greater severity of alcohol dependence has also been shown to predict poorer treatment outcome (Lindstrom 1992).

While considered to be important in the development of alcoholism, comorbid psychiatric disorders also have prognostic significance (Meyer 1986). Rounsaville et al. (1987) found that psychiatric diagnosis at the time of treatment intake predicted a variety of 1-year posttreatment outcomes. Among males, the presence of a comorbid lifetime diagnosis of ASPD, major depressive disorder, or drug abuse/dependence was associated with poorer drinking outcomes. Among females, the presence of major depressive disorder predicted a better outcome on drinking-related measures, while those patients with ASPD or drug abuse/dependence had a poorer prognosis. Three-year posttreatment outcomes in this group of alcoholics also showed comorbid ASPD, major depressive disorder, and drug abuse/dependence to be associated with poorer outcomes, irrespective of gender. It is notable, however, that at 3-year follow-up major depressive disorder was not associated with a protective effect for women alcoholics (Kranzler et al. 1996b).

Other investigators have found no difference in drinking outcomes when comparing primary alcoholics (i.e., those for whom alcohol dependence is the first and predominant disorder) and alcoholics with a comorbid mood disorder (Schuckit 1985, O’Sullivan et al. 1988, Powell et al. 1992). However, as might be expected, alcoholics with comorbid depression have greater psychiatric severity at follow-up than primary alcoholics (O’Sullivan et al. 1988, Powell et al. 1992). Variable findings have also been reported concerning the prognostic significance of ASPD and drug abuse among alcoholics. Both Powell et al. (1992) and Schuckit (1985) found that, compared with primary alcoholics, alcoholics with either primary ASPD or a primary drug abuse diagnosis (i.e., individuals in whom these disorders preceded the onset of alcohol dependence) did not differ on alcohol-related outcomes. However, in one study (Schuckit 1985), alcoholics with these primary diagnoses reported more illicit drug use and poorer social functioning during the posttreatment period. Furthermore, Liskow et al. (1990) found that alcoholics with a lifetime drug diagnosis in combination with ASPD had poorer alcohol-related outcomes.

Although a number of studies have shown that patients experience substantial improvement during the year following alcoholism treatment (Lindstrom 1992), Vaillant (1983) found that treatment had minimal effects on long-term outcome. More long-term treatment outcome studies are needed to examine the impact of different kinds of alcoholism treatment on the course of the disorder. Additional studies are also needed to clarify both the prognostic significance of patient-related variables, including comorbid psychiatric disorders, and their interaction with different kinds of treatment.

**Treatment**

**Goals, Setting, and Costs of Treatment**

When a determination has been made that an individual is drinking excessively, the nature, setting and intensity of the intervention must be determined in order to address the specific treatment needs of the patient. Among heavy drinkers without evidence of alcohol dependence, a brief intervention aimed at the reduction of drinking may suffice. In contrast, patients with alcohol dependence typically have a more complex set of needs to address, as indicated in Table 54–7.

### Table 54–7  Goals of Alcoholism Treatment

| **Promote complete abstinence from alcohol.** |
| **Stabilize acute medical (including alcohol withdrawal) and psychiatric conditions, as needed.** |
| **Increase motivation for recovery.** |
| **Initiate treatment for chronic medical and psychiatric conditions, as needed.** |
| **Assist the patient in locating suitable housing (e.g., moving from a setting in which drinking is widespread), as needed.** |
| **Enlist social support for recovery (e.g., introduce to 12-step programs and, when possible, help the patient to repair damaged marital and other family relationships).** |
| **Enhance coping and relapse prevention skills (including social skills, identification and avoidance of high-risk situations).** |
| **Improve occupational functioning.** |
| **Promote recovery through participation in structured aftercare treatment or self-help groups.** |

**Treatment Goals for Patients with Alcohol Dependence**

Figure 54–1 describes a process for the management of patients with alcohol abuse and dependence. The algorithm is written from the perspective of a community-based or consultation/liaison psychiatrist who does not necessarily
have specialized training in addiction medicine. Following the initial assessment, using a screening test like the CAGE or AUDIT, the patient is referred to either a diagnostic evaluation or a brief intervention with further monitoring. Brief interventions are characterized by their low intensity and short duration. They typically consist of one to three sessions of counseling and education. They are intended to provide early intervention, before or soon after the onset of alcohol-related problems. Brief interventions seek to motivate high-risk drinkers to moderate their alcohol consumption, rather than promote total abstinence with specialized treatment techniques. They are simple enough to be delivered by primary care practitioners and are especially appropriate for psychiatric patients whose at-risk drinking meets criteria for alcohol abuse rather than dependence.

During the past 2 decades, numerous randomized controlled trials have been conducted to evaluate the efficacy of brief interventions. The results of these trials have been summarized in several integrative literature reviews and meta-analyses (Kahan et al. 1995, Wilk et al. 1997, Poikolainen 1999, Whitlock et al. 2004). The cumulative evidence shows that clinically significant effects on drinking behavior and related problems can follow from brief interventions. Nevertheless, the results have not always been consistent across studies (Poikolainen 1999). Furthermore, there is little evidence that these interventions are beneficial for alcohol dependent individuals (Mattick and Jarvis 1994).

If the patient’s screening results and diagnostic evaluation provide evidence of alcohol dependence, the next step is to differentiate between mild and more severe levels of physical dependence to determine the need for detoxification. If withdrawal risk is low, the patient may be referred directly to outpatient therapy. If the withdrawal risk is moderate or high, outpatient or inpatient detoxification is indicated.

There are a number of potentially life threatening conditions for which alcoholics are at increased risk. The presence of any of the following requires immediate attention: acute alcohol withdrawal (with the potential for seizures and delirium tremens), serious medical or surgical disease (e.g., acute pancreatitis, bleeding esophageal varices), and serious psychiatric illness (e.g., psychosis, suicidal intent). In the presence of any of these emergent conditions, acute stabilization should be the first priority of treatment.

The presence of complicating medical or psychiatric conditions is an important determinant of whether detoxification and rehabilitation are initiated in an inpatient or an outpatient setting. Other considerations are the alcoholic’s current living circumstances and social support network. Women with children are sometimes unwilling to enter residential treatment unless their family needs are taken care of.
of. In the patient without these complicating features, the major focus should be on the establishment of a therapeutic alliance, which provides the context within which rehabilitation can occur. In addition to participation in structured rehabilitation treatment, the patient should be made aware of the widespread availability of Alcoholics Anonymous (AA) and the wide diversity of its membership.

Residential settings include hospital-based rehabilitation programs, freestanding units, and psychiatric units. With the growth of managed care in the 1990s, there was a dramatic reduction in the average length of stay for residential treatment and a shift in emphasis to less costly outpatient treatment settings. In many populations, outpatient programs produce results comparable to those of inpatient programs. Conclusions regarding equal effectiveness of inpatient and outpatient treatment must, however, be limited to clients who are appropriate for each type of program (Finney et al. 1996). Some studies comparing outpatient with inpatient treatment have not controlled for the possibility that patients who choose outpatient settings are less severely alcohol dependent, less physically ill, or less psychiatrically impaired. Inpatient treatment may be indicated when motivation is weak to continue treatment, when patients are psychotic, depressed, or suicidal, and when there are medical complications. Other factors that affect the choice of treatment setting include patients’ social stability and the number and severity of their symptoms, as well as the ability of programs to respond to individual needs. An obstacle to ambulatory treatment is the high rate of attrition usually encountered among more severely impaired alcoholics (Seixas 1983).

An obvious question is whether some treatment modalities are more cost-effective than others. In one analysis of treatment modalities used in the US, the range of treatment costs across settings was enormous, with a high of $585 per day for hospital-based care and a low of $6 per visit at social model, nonresidential programs. Nevertheless, the research evidence on the cost-effectiveness of different treatment modalities has consistently found that the more expensive modalities do not necessarily produce better treatment outcomes (Holder et al. 1991, Goodman et al. 1997).

In response to concerns about the inappropriate use of expensive residential treatment, patient placement criteria have been developed for adults and adolescents to standardize the way in which patients are assigned to different types and intensities of care. The Patient Placement Criteria for the Treatment of Substance-Related Disorders, second edition, revised, of the American Society of Addiction Medicine (2001) (ASAM) provides detailed guidelines for both adult and adolescent patient placement at five levels of care corresponding to DSM diagnostic criteria and specific admission and discharge patient characteristics. The decision to refer the patient to a particular level of care is based on the following considerations: acute intoxication and withdrawal, biomedical conditions, emotional/behavioral conditions, acceptance of treatment, relapse potential, and recovery environment.

Another approach to patient placement and treatment matching is based on the notion that patients should initially be matched to the least intensive level of care that is appropriate, and then stepped up to more intensive treatment settings if they do not respond (Institute of Medicine 1990). This approach is consistent with the ASAM criteria, which specify that inpatient treatment should not be recommended unless the patient has failed at outpatient treatment. Matching can also be guided by theoretically derived hypotheses. This strategy relies on the cumulative evidence of research to suggest the kinds of treatments most likely to produce favorable outcomes with different types of patients. An example is the assignment of patients with ASPD to cognitive behavioral treatment, based on evidence (Kadden et al. 1989) that these patients have better outcomes with structured therapy.

The possibility of rational treatment/patient matching continues to attract interest, and there is some evidence to suggest that patients with certain characteristics (e.g., severe dependence, high levels of anger, social networks that support drinking) respond marginally better to certain types of therapy (e.g., Twelve-Step Facilitation, motivational enhancement, cognitive behavioral) (Babor and Del Boca 2003, Ouimette et al. 1999). In one study, McLellan et al. (1993) compared the range and intensity of service delivery and associated outcomes in two inpatient and two outpatient substance abuse treatment programs for alcohol- or cocaine-dependent patients. In areas of patient functioning other than substance use (i.e., health, employment, family, and psychiatric), patients who were treated in programs with services that met their particular areas of need showed the greatest improvement in those areas after discharge. These findings suggest the importance of incorporating a range of services within specialized treatment facilities to meet the diverse psychosocial needs of alcoholic patients.

Despite treatment, some alcoholics relapse repeatedly. For many emergency department personnel, the multiple recidivist alcoholic has come to personify the disorder. For clinicians involved in the delivery of alcoholism rehabilitation services, these individuals’ apparent unresponsiveness to treatment may contribute to frustration and a sense of futility. Presently, long-term residential treatment appears to be the only option for alcoholics who do not respond to more limited efforts at rehabilitation. Unfortunately, the availability of such care in many states is limited as a consequence of the effort to deinstitutionalize psychiatric patients.

Finally, the importance of continuing care by means of aftercare groups, and other mutual help organizations cannot be overestimated. The value of these resources as well as the newer pharmacological and nonpharmacological interventions developed in the past 2 decades are discussed in subsequent sections of this chapter.

The Management of Alcohol Withdrawal
An important initial intervention for a substantial number of alcohol-dependent patients is the management of alcohol withdrawal through detoxification. Many patients who have experienced an alcohol-related problem may not have developed a dependence syndrome and therefore may experience no significant physiological disturbance on cessation of drinking. Other patients who have low to moderate levels of dependence are unlikely to experience serious withdrawal symptoms. However, many patients with a history of chronic drinking (especially those with prior experience of an abstinence syndrome) are likely to experience withdrawal symptoms, and for some patients, alcohol withdrawal can be
life threatening. Such diversity in symptomatology requires a diversified approach to patient management. The objectives in treatment of alcohol withdrawal are the relief of discomfort, prevention or treatment of complications, and preparation for rehabilitation. Successful management of the alcohol withdrawal syndrome provides a basis for subsequent efforts at rehabilitation.

Careful screening for concurrent medical problems is an important element in detoxification. Administration of thiamine (50–100 mg by mouth or IM) and multivitamins is a low-cost, low-risk intervention for the prophylaxis and treatment of alcohol-related neurological disturbances. Good supportive care and treatment of concurrent illness, including fluid and electrolyte repletion, are essential (Naranjo and Sellers 1986).

Social detoxification, which involves the nonpharmacological treatment of alcohol withdrawal has been shown to be effective. It consists of frequent reassurance, reality orientation, monitoring of vital signs, personal attention, and general nursing care (Naranjo and Sellers 1986). Social detoxification is most appropriate for patients in mild-to-moderate withdrawal. The medical problems commonly associated with alcoholism may substantially complicate therapy, so that care must be taken to refer those patients whose condition requires medical management.

Increasingly, detoxification is being done on an ambulatory basis, which is much less costly than inpatient detoxification (Hayashida et al. 1989). Inpatient detoxification is indicated for serious medical or surgical illness, and for those individuals with a past history of adverse withdrawal reactions or with current evidence of more serious withdrawal (e.g., delirium tremens).

A variety of medications have been used for the treatment of alcohol withdrawal. However, due to their favorable side effect profile, the benzodiazepines have largely supplanted all other medications (Naranjo and Sellers 1986). Although any benzodiazepine will suppress alcohol withdrawal symptoms, diazepam and chloridiazepoxide are often used, since they are metabolized to long-acting compounds, which in effect are self-tapering. Because metabolism of these drugs is hepatic, impaired liver function may complicate their use. Oxazepam and lorazepam are not oxidized to long-acting metabolites and thus carry less risk of accumulation.

Although carbamazepine appears useful as a primary treatment of withdrawal (Malcolm et al. 1989), the liver dysfunction that is common in alcoholics may affect its metabolism, which makes careful blood level monitoring necessary. Antipsychotics are not indicated for the treatment of withdrawal except in those instances where hallucinations or severe agitation are present (Naranjo and Sellers 1986), in which case they should be added to a benzodiazepine. In addition to their potential to produce extrapyramidal side effects, antipsychotics lower seizure threshold, which may be particularly problematic during alcohol withdrawal.

**Therapeutic Modalities: Nonpharmacological**

A variety of treatment components are delivered within the context of rehabilitation services. In many programs a combination of therapeutic interventions is provided to all clients, based on the assumption that multiple components have a greater chance of meeting at least some of each client’s needs. Therapeutic approaches most often employed in both residential and outpatient programs include behavior therapy, group therapy, family treatment, and pharmacotherapy. Regarding specific treatment modalities, the weight of evidence suggests that behavioral treatments are likely to be more effective than insight-oriented or family therapies (Miller and Hester 1986). Nevertheless, recent research (Babor et al. 2003, Ouimette et al. 1999) also indicates that Twelve-Step Facilitation, which is based on the principles of AA, is as effective as more theory-based therapies. Controlled studies provide little support for the effectiveness of psychodynamic psychotherapy, although such treatment has been shown to be helpful in the treatment of drug abuse (Institute of Medicine 1989).

Cognitive and behavior therapies are among the most investigated theory-based treatments. Behavioral elements most frequently employed in treatment programs are relapse prevention, social skills training, contingency management and cognitive restructuring. Aversion therapy, based on Pavlovian conditioning theory has been virtually abandoned in the USA. Although it has been shown that the sight, smell, and taste of alcohol will acquire aversive properties if repeatedly paired with noxious stimuli (e.g., chemically-induced nausea and vomiting), the procedure is expensive and has not been shown to be superior to less heroic methods.

Behavior therapists stress the importance of teaching new, adaptive skills designed to alter the conditions that precipitate and reinforce drinking, as well as developing alternative ways of coping with persons, events, and feelings that serve to maintain drinking. A number of studies have demonstrated the benefits of teaching social and other coping skills (Institute of Medicine 1990). One example of this approach in “relapse prevention” which focuses on identifying and coping with situations that represent high risk for heavy drinking. Research on cognitive–behavioral treatments (Institute of Medicine 1989) have provided the empirical basis for elaboration of a generalized relapse prevention strategy (Marlatt 1985).

The deleterious effects of alcoholism on marriages and families have been a source of concern to both clinicians and researchers. Alcoholism creates major stress on the family system by threatening health, interpersonal relations, and the economic functioning of family members. Although research has shown a strong association between healthy family functioning and positive outcome following alcoholism treatment (Moos and Moos 1984), little systematic evaluation has been undertaken to assess the efficacy of family approaches, either to reduce alcohol problems or to improve family functioning.

Most studies have involved marital rather than family treatment. A trial of behavioral marital therapy was conducted by O’Farrell et al. (1985). Alcoholics and their spouses were treated in aftercare for 10 weeks. At follow-up, behavioral marital therapy was found to have enhanced marital well-being more than did interactional couples therapy, while a no-marital-therapy control group showed no significant change. There was no differential improvement in drinking behavior among the three groups. Subsequently, McCrady et al. (1986) showed behavioral marital therapy to be superior to control treatments in both the reduction of drinking and maintenance of sobriety.
In addition to specific treatment for alcoholic couples or family members, self-help groups for family members of alcoholics have grown substantially. Al-Anon, although not formally affiliated with AA, shares the structure and many of the tenets of the 12 Steps of AA. Al-Anon and AA meetings are often held jointly. Alateen groups, sponsored by Al-Anon for children of alcoholics, are available as well.

**Therapeutic Modalities: Pharmacological**

Although the benzodiazepines have played a key role in the treatment of alcohol withdrawal, pharmacotherapy has not yet had a demonstrable effect on other aspects of alcoholism treatment. Disulfiram, an alcohol-sensitizing drug, has been approved for clinical use in the US since the 1940s, but it has not been widely prescribed. During the past decade, however, medications have begun to play a more important role both in the treatment of comorbid psychiatric disorders in alcoholics and in the rehabilitation of alcohol dependence. In dually diagnosed patients, medications that reduce psychiatric symptomatology may also reduce the risk of drinking. Independent of their effects on comorbid psychopathology, medications that reduce drinking may enhance the alcoholic’s participation in psychosocial treatment. This rationale is similar to that underlying the combination of medications with psychotherapy in the treatment of depressive or anxiety disorders.

In the following sections, we discuss three types of pharmacotherapy for alcoholics: alcohol-sensitizing drugs, medications to treat comorbid psychopathology, and medications to directly reduce drinking. The reader is referred to detailed reviews of these topics for additional information (Swift 1999, Garbutt et al. 1999, Kranzler 2000).

**Alcohol-Sensitizing Drugs**

Medications such as disulfiram or calcium carbimide cause an unpleasant reaction when combined with alcohol. The efficacy of such drugs in the prevention or limitation of relapse in alcoholics has not been demonstrated. However, these drugs may be of utility in selected samples of alcoholics with whom special efforts are made to ensure compliance.

Disulfiram (Antabuse) is the most commonly used alcohol-sensitizing medication and the only one approved for use in the US. When given in a single daily dose of 125–500 mg, disulfiram binds irreversibly to ALDH, permanently inactivating this enzyme. When alcohol is consumed, it is metabolized to acetaldehyde which accumulates due to inhibition of the enzyme that metabolizes it. Elevated levels of acetaldehyde are responsible for the aversive effects associated with the disulfiram-ethanol reaction (DER).

In addition to its effects on ALDH, disulfiram inhibits a variety of other enzymes. Disulfiram also reduces clearance rates of a number of medications. Common side effects of disulfiram include drowsiness, lethargy and fatigue (Chick 1999). More serious adverse effects, such as optic neuritis, peripheral neuropathy, and hepatotoxicity are rare. The exacerbation of psychotic symptoms in patients with schizophrenia, and occasionally their appearance in other individuals as well as the development of depression may be linked to inhibition of the enzyme dopamine-beta-hydroxylase. As with its neuropsychiatric effects, the psychiatric effects of disulfiram are uncommon and may only occur at higher dosages of the medication.

Although disulfiram has been used in the treatment of alcoholism for more than 50 years, the few placebo-controlled studies that have been conducted have not shown the drug to have substantial efficacy. In a multicenter trial conducted by the U.S. Department of Veterans Affairs (VA) more than 600 male alcoholics were assigned randomly to groups receiving either 1 mg of disulfiram/day or 250 mg/day, or to a control group that was told they were not receiving disulfiram (Fuller et al. 1986). Results revealed a direct relationship between compliance with any of the three treatment regimens and complete abstinence. Among patients who resumed drinking, those taking the 250-mg dosage of disulfiram had significantly fewer drinking days than did patients in the other two groups. However, there was no significant difference among the three groups with respect to a variety of outcome measures, including length of time to first drink, unemployment, social stability, or number of men totally abstinent.

Disulfiram is usually given orally. Although the daily dosage prescribed in the US has been limited to 250–500 mg/day, some patients require in excess of 1 g/day of disulfiram to reach blood levels sufficient to produce the DER (Brewer 1984). The requirement that disulfiram undergo bioactivation before it can inhibit ALDH (Yourick and Faiman 1991) may explain the need for a higher dosage in some patients. At the dosage that is used clinically, faulty bioactivation in some individuals may yield too low a concentration of the active metabolite to inhibit ALDH.

Many practitioners believe that by enhancing compliance with disulfiram it is possible to increase the individual’s commitment to abstinence from alcohol. Depot formulations would remove the need for voluntary compliance but they have not been shown to be reliable and are not approved by the Food and Drug Administration (FDA). However, a variety of approaches to enhancing voluntary compliance with disulfiram therapy have been employed (Allen and Litten 1992). These include the use of incentives, contracting with the patient and a significant other to promote the patient's taking disulfiram, providing additional information to the patient, behavioral training, and social support.

Azrin et al. (1982) found that disulfiram was superior to placebo when combined with a program of stimulus control training, role playing, communication skills training, and recreational and vocational counseling. Chick et al. (1992) compared supervised disulfiram treatment with placebo as an adjunct to the outpatient treatment of alcoholism. Under these circumstances, disulfiram significantly increased abstinent days and decreased total drinks consumed. Supervised adherence may be an essential element in the successful use of disulfiram (Brewer et al. 2000). Because substantial efforts are required to promote adherence to a disulfiram regimen (Azrin et al. 1982), use of the drug outside of a well-organized treatment program is probably unwarranted.

Given the limited efficacy of disulfiram for the prevention of relapse, it should not be used as a first line treatment for alcohol dependence. However, if a patient has not responded to other pharmacological treatments and is motivated to take disulfiram, it may be beneficial. Whenever disulfiram is prescribed, patients should be warned about its hazards, including the need to avoid over-the-counter (OTC) preparations with alcohol and drugs that interact adversely.
with disulfiram, as well as the potential for a DER to result from alcohol used in food preparations.

The Treatment of Psychiatric Comorbidity in Alcoholics

Comorbid psychiatric disorders may contribute to the development or maintenance of heavy drinking (Meyer 1986). Efforts to treat the comorbidity may have beneficial effects on drinking outcomes. Following detoxification, many alcoholics complain of persistent anxiety, insomnia, and general distress. These symptoms may last for weeks or months and may be difficult to differentiate from the emergence of diagnosable psychiatric disorders. Irrespective of their etiology, negative emotional states, including frustration, anger, anxiety, depression, and boredom, have been shown to contribute to relapse in a substantial proportion of alcoholics (Marlatt 1985).

A variety of medications have been employed to treat comorbid psychiatric symptoms and disorders in alcoholics. Indications for the use of these medications in alcoholics are similar to those for nonalcoholic populations, but there is added potential for adverse effects due to comorbid medical disorders and the pharmacokinetic effects of acute and chronic alcohol consumption. The use of these medications in alcoholics therefore entails additional considerations that can only be arrived at through careful psychiatric diagnosis.

Treatment of Depressive Symptoms Disorders

Depressive symptoms are common early in alcohol withdrawal, but they often remit spontaneously with time (Dorus et al. 1987). For depression that persists beyond the period of acute withdrawal, an antidepressant is probably warranted. In general, placebo-controlled trials of tricyclic antidepressants (TCAs) in depressed alcoholics have not provided evidence of efficacy. Research in this area, however, was characterized by substantial methodological limitations (Ciraulo et al. 1982). Most studies of TCAs in depressed alcoholics used a therapeutically inadequate dosage of the medication, with no effort made to compensate for the fact that both cigarette smoking and heavy drinking can stimulate liver enzymes that metabolize drugs. Placebo-controlled trials of imipramine (Nunes et al. 1993, McGrath et al. 1996) and desipramine (Mason et al. 1996), which take these considerations into account, suggest that TCAs reduce depressive symptoms in depressed alcoholics.

In a study of alcoholics with secondary depression (i.e., depression that was present prior to the onset of alcohol dependence), in which desipramine or placebo treatment was initiated after eight days of abstinence (Mason et al. 1996), the active drug was found to be superior in reducing both depressive symptoms and heavy drinking. The time course of the response suggests that the common practice of requiring a period of 2–4 weeks before initiating antidepressant therapy may be excessive.

There are a limited number of studies using selective serotonin reuptake inhibitors (SSRIs) in the treatment of major depressive disorder in alcoholics. In a placebo-controlled trial of fluoxetine for relapse prevention in alcoholics (Kranzler et al. 1995), individuals with current major depressive disorder who received the active medication showed a greater reduction in depressive symptoms than those receiving placebo. In a 12-week study (Cornelius et al. 1997), fluoxetine was superior to placebo in reducing both depressive symptoms and total alcohol consumption in patients diagnosed with major depressive disorder and alcohol dependence. Sertraline has also been shown to reduce depressive symptoms among inpatient alcoholics, although the medication’s effects on preventing relapse to drinking have not been evaluated (Roy 1998). The serotonergic antidepressant nefazodone has also been shown in one study (Roy-Byrne et al. 2000) to reduce depressive symptoms in depressed alcoholics, but no direct effect on drinking behavior was observed.

Early studies of lithium (Kline et al. 1974, Merry et al. 1976) showed that patients treated with the drug experienced fewer days of pathological drinking than those receiving placebo. However, a multicenter double blind placebo-controlled trial (Dorus et al. 1989) in 457 male alcoholics, of whom approximately one-third were depressed, found no significant differences between lithium-treated and placebo-treated patients on any outcome measures, including number of drinking days, alcohol-related hospitalizations, and severity of depression. The lack of efficacy was observed for both the depressed and the nondepressed groups. This large, carefully conducted trial suggests that if lithium has a role in alcoholism treatment, it is probably limited to the treatment of those alcoholics with comorbid bipolar disorder. A study by Fawcett et al. (2000), in which there was no advantage to lithium over placebo in alcoholics who were not selected for a comorbid psychiatric disorder, is consistent with this conclusion. In summary, although it has been argued that most instances of postwithdrawal depression will spontaneously remit within a few days to several weeks (Schuckit 1983, Brown and Schuckit 1988), there is still a substantial number of patients whose severe and persistent depression requires treatment. Given the superior safety profile of SSRIs, particularly in relation to risk of suicide by medication overdose, use of these drugs is preferable to the use of TCAs.

Treatment of Anxiety Symptoms/Disorders

A number of studies have shown clordiazepoxide to be effective in the maintenance of alcoholics in long-term outpatient treatment (Kissin 1975, Rosenberg 1974). However, the potential for additive CNS depression produced by the concurrent use of alcohol and benzodiazepines is well recognized. Furthermore, the use of benzodiazepines may itself result in tolerance and dependence and may increase depressive symptoms (Schuckit 1983). Although this concern may be exaggerated (Ciraulo et al. 1988) and all benzodiazepines may not be equal in their capacity to produce dependence in alcoholics (Jaffe et al. 1983), generally speaking, the use of benzodiazepines in alcoholics is probably best limited to detoxification.

Buspiron (Taylor et al. 1985) is a nonbenzodiazepine anxiolytic that is less sedating than diazepam or clorazepate, does not interact with alcohol to impair psychomotor skills, and has a low potential for abuse. A double blind, placebo-controlled trial of buspiron in alcoholics (Bruno 1989) found significantly greater retention in treatment and greater decreases in alcohol craving, anxiety, and depression in buspiron-treated patients. Both groups showed significant declines in drinking. Similarly, Tollefsen et al. (1992) found that buspiron-treated subjects were less likely to discontinue...
A number of specific neurotransmitter systems have been implicated in the control of alcohol consumption, including endogenous opioids, catecholamines, especially dopamine, and serotonin. Although these systems appear to function interactively in their effects on drinking behavior, efforts to use medications to treat excessive drinking have increasingly focused on agents that have selective effects on specific neurotransmitter systems.

**Opioid Antagonists**

An extensive literature supports the role of opioidergic neurotransmission in the pathophysiology of alcohol consumption and related phenomena. For example, small doses of morphine increase alcohol intake in experimental animals (Hubbell et al. 1986). In contrast, opioid antagonists, such as naltrexone, decrease ethanol consumption and self-administration (Sivy et al. 1982). Effects similar to those in animals have been reported in some, but not all, studies of naltrexone for the treatment of alcohol dependence (Kranzler and Van Kirk 2001). The considerable variability in findings concerning the efficacy of naltrexone underscores the need to identify the circumstances under which the medication exerts its therapeutic effects.

In the first double blind, placebo-controlled trial, Volpicelli et al. (1992) found that naltrexone was superior to placebo in delaying the time to relapse and reducing the rate of relapse to heavy drinking among patients in a VA treatment program. Naltrexone did not affect subjects’ “sampling” of alcohol, but reduced the return to heavy drinking following consumption of a small amount of alcohol. In this study, naltrexone also reduced patients’ reported desire for alcohol. The results suggested that naltrexone may be particularly useful for subjects who present with high levels of craving and somatic symptoms (Volpicelli et al. 1995).

These findings were replicated and extended in a study that examined the utility of naltrexone in combination with two different psychotherapies (O’Malley et al. 1992). In that study, naltrexone was more efficacious in preventing the initiation of drinking when paired with supportive therapy than when used in combination with coping skills training. On the other hand, once the subject sampled alcohol, naltrexone plus coping skills/relapse prevention training was better at preventing a full-blown relapse, indicating that the efficacy of naltrexone was enhanced by teaching subjects specific strategies for avoiding alcohol (O’Malley et al. 1992). Individuals with higher levels of craving and poorer cognitive functioning derived the greatest benefit from naltrexone compared with placebo (Jaffe et al. 1996). During a 6-month posttreatment follow-up period, the beneficial effects of naltrexone diminished gradually over time (O’Malley et al. 1996).

Kranzler et al. (1998) found that alcoholics treated with a sustained-release (i.e., depot) formulation of naltrexone had detectable plasma concentrations of the drug for more than 30 days following injection. Furthermore, the active formulation was superior to placebo in reducing the frequency of heavy drinking in these subjects. However, in a subsequent study, these investigators (Kranzler et al. 2000) found no advantage for oral naltrexone over placebo on measures of alcohol consumption. In this study, naltrexone treatment was associated with a high rate of adverse events. Though there were no serious adverse events, the ones that were observed decreased the rates of both medication compliance and study completion (Oncken et al. 2001).

In contrast, Anton et al. (1999) found that naltrexone in combination with cognitive–behavioral therapy was superior to placebo in reducing the percentage of days abstinent, number of drinks per drinking day, and time to relapse to heavy drinking during a 12-week treatment trial. During a 14-week, posttreatment follow-up period, these subjects showed a gradual increase in relapse rates, drinking days, and heavy drinking days (Anton et al. 2000), and the difference between naltrexone and placebo treatments was not statistically significant. Consistent with the results reported by O’Malley et al. (1996), these findings suggest that treatment with naltrexone is warranted for longer than 12 weeks. Results from a multicenter, 12-week trial of naltrexone treatment for alcohol abuse and dependence showed no effects on drinking outcomes (Chick et al. 2000a). However, among compliant subjects, naltrexone was superior to placebo on a number of alcohol-related outcomes.

Two additional studies showed positive effects of naltrexone, particularly on heavy drinking. Monterosso et al. (2001) compared naltrexone 100 mg/day with placebo in the first 12-week phase of a multiphase double blind trial. Naltrexone was superior to placebo on the number of heavy drinking days. In addition, individuals with a high pre-treatment level of craving and those with high familial loading for alcoholism were more likely to benefit from naltrexone treatment. Heimala et al. (2001) compared naltrexone 50 mg/day with placebo, study medication being paired with either coping skills or supportive therapy. During
the initial 12 weeks of treatment, they found an advantage for naltrexone in preventing relapse to heavy drinking only when combined with coping skills therapy. During a subsequent 20-week period, when subjects were given the same medication, they were told to use it only when they craved alcohol (i.e., “targeted treatment”; Kranzler et al. 1997). Beneficial effects of the medication that were observed during the initial period of daily treatment were generally sustained with targeted treatment. These results suggest that concomitant coping skills therapy is needed if naltrexone is to reduce heavy drinking (Heinala et al. 2001). The investigators also observed that an initial period of abstinence is not required for the medication to be efficacious and that naltrexone targeted to alcohol craving is effective in maintaining the reduction in heavy drinking following a period of daily medication (Heinala et al. 2001).

Morris et al. (2001) conducted a trial of naltrexone in male alcoholics in Australia. Treatment with the active medication or placebo was combined with a weekly skills group. In the total sample, fewer naltrexone-treated patients relapsed to heavy drinking. Among patients completing the 12-week trial, naltrexone treatment reduced total alcohol consumption. Monti et al. (2001) examined the effects of naltrexone in combination with two different psychotherapeutic interventions in a 12-week trial in which patients were recruited from a partial hospital treatment program. Although they found no effects of the active medication, among patients who were medication compliant on at least 70% of days, naltrexone treatment resulted in fewer heavy drinking days and fewer drinks/drinking day than placebo. In a multicenter trial conducted in the VA (Krystal et al. 2001), more than 600 veterans with severe alcohol dependence were randomly assigned to receive 12 months of naltrexone, 3 months of naltrexone followed by 9 months of placebo, or 12 months of placebo. There were no significant group differences at either the 3-month or the 12-month evaluation points. In contrast to most of the other studies of naltrexone, the VA study used 12-Step facilitation therapy, rather than coping skills psychotherapy. In addition, the severity of the subjects’ alcohol dependence was greater than in most previous studies. Consequently, these findings have limited relevance to the outpatient treatment of non-veterans, particularly when coping skills psychotherapy is employed.

Another opioid antagonist, nalmefene, has also been evaluated in alcohol-dependent subjects. In an initial pilot study (Mason et al. 1994) and a subsequent larger trial (Mason et al. 1999), the medication was shown to be well tolerated and to be superior to placebo in reducing relapse. The most comprehensive clinical trial to date of naltrexone therapy is the Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study conducted at 11 sites with nearly 1,400 patients (Anton et al. 2006). The study explored a variety of treatment methods—a lone and in combination—within the context of medical management. Naltrexone in combination with a brief behavioral therapy delivered by licensed health care professionals was more effective than more intensive behavioral therapy. Naltrexone was associated with more abstinent days and reduced the risk of a heavy drinking day after a relapse. The effects, however, tended to be short-lived, with no advantage evident 1-year later after medication had been suspended.

The findings from this study underscore the notion that naltrexone with medical management potentially may be delivered by primary care clinicians who frequently deal with alcoholic patients not having access to traditional alcohol treatment programs.

In summary, naltrexone appears to produce a modest effect on drinking behavior among alcoholics (Kranzler and Van Kirk 2001). However, given the comparatively small overall effect of the medication, a variety of other factors, including medication compliance, the severity and chronicity of alcohol dependence, and the choice of concomitant psychotherapy, may determine whether an effect of the medication is observed.

**Serotonergic Medications**

Another major focus of research on medications to treat alcoholism has been the role of the indoleamine neurotransmitter, serotonin (5-HT). 5-HT has been shown consistently to exert an influence over alcohol consumption in preclinical models of drinking behavior (LeMarquand et al. 1994a) but, data on human drinking are less consistent (Kranzler 2000). Naranjo et al. (1990) found that fluoxetine 60 mg/day reduced average daily alcohol consumption by approximately 17% from baseline levels, while treatment with fluoxetine 40 mg/day or placebo had no effect. But a placebo-controlled trial of fluoxetine 60 mg/day in combination with coping skills psychotherapy in outpatient alcoholics showed no overall advantage to the active drug on drinking outcomes (Kranzler et al. 1995). Kabel and Petty (1996) showed no effect of fluoxetine 60 mg/day, compared with placebo, among veterans with severe alcoholic problems.

Another SSRI whose effects on alcohol consumption have been extensively examined is citalopram. At a dosage of 40 mg/day, citalopram was initially reported to reduce the number of drinks consumed per day and increase the number of abstinent days in a sample of nondepressed, early-stage problem drinkers (Naranjo et al. 1987). Using a similar design, these findings were replicated (Naranjo et al. 1992). However, Baldin et al. (1994) found no effect of citalopram 40 mg/day on alcohol intake among heavy drinkers.

One explanation for the variable findings in studies of whether SSRIs reduce drinking is the diversity of study samples. The initial studies were conducted in nontreatment-seeking heavy drinkers. Subsequent studies, which have shown differential effects based on severity, suggest that SSRIs are efficacious only in subgroups of alcoholics. For example, Gerra et al. (1992) found an effect of fluoxetine only in alcoholics with a positive family history of alcoholism. In contrast, Kranzler et al. (1996a) found that high-risk/severity alcoholics (i.e., Type B, who have an earlier age of alcoholism onset, more sociopathic features, greater concomitant drug use) had poorer drinking outcomes when treated with fluoxetine, compared with placebo, and that low risk/severity alcoholics (Type A) had somewhat better outcomes on the active medication. Baldin et al. (1994) found an effect of citalopram only among drinkers in the lower range of alcohol consumption in their patient sample. Pettinati et al. (2000) found that later-onset alcoholics drank on fewer days and were more likely to be abstinent in a 12-week treatment trial if they received sertraline than if they were treated with placebo.
In a similar vein, although not an SSRI, ondansetron (a 5-HT3 antagonist) was shown to produce a selective beneficial effect in alcoholics with onset of problem drinking before age 25 (Johnson et al. 2000). At a dosage substantially lower than that used to exert the anti-emetic effects for which the medication is FDA approved, ondansetron was superior to placebo in terms of days abstinent and the intensity of alcohol intake on days when patients did drink. Among alcoholics with onset of problem drinking at age 25 years or later, the effects of ondansetron on drinking behavior were, in nearly all respects, comparable to those of placebo. These findings suggest that prospective studies that aim to match alcoholic subtypes with serotonergic medications may reveal a useful role for such medications in the treatment of alcohol dependence, but the evidence to date does not support their use of SSRIs in routine clinical practice.

**Acamprosate**

Acamprosate, an amino acid derivative, affects both gamma-aminobutyric acid (GABA) and excitatory amino acid (i.e., glutamate) neurotransmission (the latter effect most likely being the one that is important for its therapeutic effects in alcoholism). The medication is approved for use throughout Europe, and in the US since 2005.

Multicenter studies have been conducted in Belgium, the Netherlands and Luxembourg (Geerlings et al. 1997), Austria (Whitworth et al. 1996), Germany (Sass et al. 1996), and Italy (Poldrugo 1997, Tempesta et al. 2000). All of these studies showed significant advantages for acamprosate over placebo. However, in a study conducted in the UK (Chick et al. 2000b), no beneficial effects of the active drug on drinking behavior were observed. Moreover, the COMBINE study (Anton et al. 2006) found no significant effect of acamprosate on drinking vs. placebo, either by itself or with any combination of naltrexone and cognitive behavioral therapy.

Acamprosate does not interact with alcohol or diazepam. It has no addictive potential and can be used safely with antidepressants. It should not be prescribed to patients with renal insufficiency or severe hepatic failure, nor to women who are pregnant or breast-feeding. Given the rather consistent evidence of the efficacy of acamprosate in alcoholism rehabilitation (Kranzler and Van Kirk 2001), and the benign side effect profile of the medication, it appears to hold considerable value for the treatment of alcohol dependence.

**Summary**

Additional research is required before medications are likely to play a meaningful role in the postwithdrawal treatment of alcohol dependence. One currently useful strategy is the identification of comorbid psychopathology in alcoholics, with pharmacotherapy directed toward reducing both psychiatric symptoms and alcohol consumption. In addition, the opioid antagonist naltrexone, which is capable of yielding a modest effect overall in reducing drinking behavior, appears to be of considerable value in some individuals. Further research is required with naltrexone to determine the optimal dosage, duration of treatment, and psychosocial treatment strategies with which to use the medication. The question of whether the medication is most efficacious for alcoholics with high levels of craving for alcohol remains an important one. The SSRIs fluoxetine, citalopram, and sertraline may be of value in subgroups of heavy drinkers, particularly those with a later onset of problem drinking. In contrast, ondansetron may be useful in alcoholics with an early onset of problem drinking. Prospective replication of this serotonergic matching strategy is required, however, before it can be recommended for general clinical use. Finally, acamprosate may be useful in the pharmacological management of alcohol dependence but further research is required to explain why the COMBINE study failed to replicate previous findings.

**AA and Mutual Help Organizations**

Although mutual help societies composed of recovering alcoholics are not considered a formal treatment, they are often used as a substitute, an alternative, and an adjunct to treatment (McCray and Miller 1993). Mutual help groups based on the 12 Steps of AA have proliferated throughout the world. To the extent that AA and other mutual help groups are more numerous than outpatient treatment, they may constitute a significant resource for problem drinkers who are attempting to reduce or stop drinking.

With an estimated 100,000 groups and more than 2.2 million members in 150 countries, AA is by far the most widely utilized source of help for drinking problems in the US (Humphreys 2004). In addition, a number of self-help organizations have modeled themselves after AA, basing recovery from drug abuse, overeating, and other behavioral disorders on the 12 Steps of AA (see Table 54–8). Unfortunately, clinicians often refer patients to self-help groups such as AA without consideration of the patient’s needs and without adequate monitoring of the patient’s response (Emrick 1994). Not all people are willing to endorse the AA emphasis on spirituality and its disease concept of alcoholism, which requires lifelong abstinence as the only means to recovery. Greater familiarity with AA may help clinicians to identify those patients who might benefit from this approach.

Although it is regarded as one of the most useful resources for recovering alcoholics, the research literature supporting the efficacy of AA is limited (Miller and McCray 1993). Attendance at AA tends to be correlated with long-term abstinence (Vaillant 1983, Humphreys 2004) but this may reflect motivation for recovery. The type of motivated alcoholic that persists with AA might do just as well with other forms of supportive therapy. In fact, the few random assignment studies that have been conducted (Walsh et al. 1991, Brandsma et al. 1980) do not indicate that AA (or similar programs) is more effective than other types of treatment.

Personality variables do not appear to differentiate between alcoholics who affiliate with AA and those who do not (Ogborne and Glaser 1981), although there is some evidence that AA is less successful among persons with major psychiatric disorders and those of low socioeconomic status (Ogborne and Glaser 1981).

Infrequent attempts have been made to assess the efficacy of AA using controlled research designs because of methodological challenges, such as self-selection and ethical concerns about random assignment to treatment.
The 12 Steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God as we understand Him.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong, promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics, and to practice these principles in all our affairs.

---

**Psychiatric Comorbidity**

There is considerable evidence that links the outcome of alcoholism treatment to comorbid psychopathology. General measures of psychopathology (McLellan et al. 1983), as well as the specific diagnoses of drug abuse, drug dependence, ASPD and major depressive disorder have been shown to predict poorer outcomes in alcoholics (Rounsaville et al. 1987, Kranzler et al. 1996b). The extent to which treatment of comorbid psychopathology enhances alcoholism treatment outcome is unclear.

Some discussion has already been provided concerning the pharmacotherapeutic approach to treating comorbid psychiatric disorders in alcoholics. Such pharmacotherapy should be considered within the context of a more generalized approach, given the interactional nature of psychiatric and addictive disorders. Ries (1993) has distinguished among serial, parallel and integrated models for treating these disorders. The serial model involves the treatment of one disorder, followed by the treatment of the second disorder. For example, a psychotic alcoholic might first be treated on a general psychiatric unit and once his acute psychosis is controlled, transferred to an alcoholism rehabilitation program. The parallel treatment approach involves concurrent, but separate, treatment of both the psychiatric and the alcohol use disorder. An example of this approach would be the case of a depressed alcoholic who is seen in an addictions program biweekly for his alcohol dependence, but who receives medication and weekly cognitive therapy for depression in a psychiatric clinic. The integrated model involves the treatment of both disorders in a single treatment setting at the same time. This approach requires that personnel with expertise in both the addictions and psychiatric treatment be available in a single location. Each of these approaches has advantages and disadvantages. For example, the integrated model, while it provides the most comprehensive approach, is the most difficult and costly to configure and may, therefore, not be feasible for many treatment providers.

Osher and Kofoed (1989), in advocating an integrated approach to patients with comorbid psychiatric and addictive disorders, have described four phases of treatment with this patient population: (1) engagement of dually diagnosed patients in the treatment programs, (2) persuading these patients to accept long-term abstinence as an appropriate goal of treatment, (3) active treatment, during which efforts are focused on the development of attitudes and the acquisition of skills necessary for sobriety, and (4) relapse prevention, which involves the long-term maintenance of sobriety and extends beyond the acute treatment period.

**Demographic Features**

**Adolescents**

Despite a paucity of controlled, age-specific treatment outcome studies of adolescents with alcohol use disorders, the need for prevention and specialized treatment for this group is clear. The literature indicates that in substance-abusing adolescents some treatment is better than no treatment, relapse rates are high, and there is no consistent support for the superiority of any single treatment approach. However, several recent studies have described a number of factors that influence the success of adolescents addicted to alcohol. These factors include genetic predisposition, environmental influences, and systemic variables that interact to produce a unique set of challenges for adolescents and their families.
modality (Brown et al. 1989). However, several factors have been associated with better treatment outcome: later onset of problem drinking, pretreatment attendance at school, voluntary entrance into treatment, active parental input, and availability of ancillary adolescent-specific services, including those pertaining to school, recreation, vocational needs, and contraception (Kaminer 1994, Catalano et al. 1990–1991).

Brown et al. (1989) found that the adolescents who relapsed following inpatient treatment did so most frequently (60%) in response to social pressures to drink or use drugs, with 33% indicating that their relapse was an attempt to cope with negative affect and 27% identifying interpersonal conflict as a precursor to relapse. Accordingly, relapse prevention techniques, including social skills training (e.g., assertiveness techniques, communication skills, strategies for controlling anger) and techniques for managing high-risk situations may be particularly useful for adolescents (Kaminer 1994).

Because many adolescents have not yet fully developed formal operational thinking, treatment efforts should be concrete and goal oriented. Furthermore, the clinician should consider the potential impact on treatment of other cognitive problems: learning disabilities, attention-deficit/hyperactivity disorder, and other psychopathology which may previously have gone undiagnosed. Treatment of the adolescent with an alcohol use disorder also requires an appreciation of the importance of modeling, imitation and peer pressure, which are intrinsic to identity development. The use of age-appropriate support groups (e.g., Alateen) may be particularly useful in this regard.

Geriatric Patients
In addition to the high prevalence of medical problems, pharmacokinetic and pharmacodynamic variables can affect treatment outcome in elderly alcoholics. For example, Liskow et al. (1989) found that elderly alcoholics, despite having drunk less than younger patients during the month prior to admission, had more severe alcohol withdrawal symptomatology and required a higher dosage of chlordiazepoxide. These investigators speculated that the observed differences might delay the entry of elderly alcoholics into rehabilitation.

A wide variety of treatment approaches (Ofman 1992) have been adapted to suit the needs of the elderly alcoholic, ranging along a continuum of intensity that includes multidisciplinary inpatient treatment programs, outpatient individual therapy, group therapy or day treatment, and outpatient recovery support groups. Despite evidence that among the elderly early-onset alcoholics show greater severity than late-onset alcoholics, outcomes following treatment are not substantially different for these groups (Ofman 1992). Treatment programs with experience in treating the elderly alcoholic are better able to coordinate rehabilitation with medical and social service providers, including case management and home visits (Ofman 1992). These programs may also be best able to provide specialized peer treatment for elderly alcoholics.

An important question in treating elderly alcoholics is the extent to which specialized treatment services improve outcome. Kofod et al. (1987) found that patients treated in special elderly peer groups remained in treatment longer and were more likely to complete treatment than those treated in mixed-age groups. These investigators concluded that elder-specific treatment has differential therapeutic value.

Changes in the demographic features of AA participants (Blazer 1989) suggest that the current cohort of elderly alcoholics has less experience with self-help groups at a time when AA is attracting younger members who are more likely to have comorbid drug abuse/dependence. As a consequence, the elderly can be expected to experience increased difficulty affiliating with AA. This, along with evidence indicating an advantage for age-specific treatment in the elderly, suggests that special efforts should be made to help the elderly alcoholic locate AA meetings that include a substantial proportion of older participants. Age-appropriate AA groups may be especially beneficial to the older alcoholic who is isolated and lonely and for whom the prospect of helping others may help to combat feelings of uselessness (Blazer 1989).

Gender (Including Pregnancy)
As described above, epidemiological and clinical studies have shown that alcohol abuse and dependence have become quite common among women, as historical gender differences in drinking problems have diminished during the past 25 years. This trend has promoted greater awareness of the impact of alcohol use on women's health and the importance of gender as a potential determinant of treatment outcome. Nonetheless, the vast majority of studies related to alcohol use and its effects, including the diagnosis and treatment of alcohol dependence, have involved men (Nixon 1993, Lex 1992). The recent requirement by the National Institutes of Health and the FDA that women and minorities be actively recruited to participate in health-related research should help to increase knowledge about alcoholism treatment outcome in these groups.

To guide the treatment of alcoholism in women, Blume (1992) suggests that evaluation should include special attention to the identification of physical abuse, sexual abuse, medical problems, psychiatric comorbidity, the presence of alcoholism and drug abuse in spouses, and alcohol-related birth defects in children. To enable women with children to participate in treatment, the availability of childcare services is critical, although it must generally be arranged independent of treatment. Blume (1992) also lists the following special treatment needs of women: information about the effects of substance use on the fetus, parenting skills, couples and family therapy, sober female role models, assertiveness training, and an awareness of sexism and its consequences. Special care must also be taken to avoid creating iatrogenic drug dependence in women (e.g., through the use of benzodiazepines to treat comorbid anxiety and depressive symptoms). While these are useful guidelines for treating alcoholic women, empirical research is needed to evaluate these and other issues more systematically.

Ethnic and Cultural Issues and Treatment
In 1991 approximately two-thirds of patients in alcoholism treatment were white, 17% were black and 12% were Hispanic (U.S. Department of Health and Human Services 1994). Although socioeconomic and cultural issues should be addressed in alcoholism treatment (Franklin 1989),
guidelines for such treatment are based largely on common sense, rather than systematic outcome evaluation. Obviously, where language barriers exist, special efforts must be made to ensure adequate communication. Treatment providers should also be aware of their patients’ traditional patterns of drinking, how drinking may be influenced by acculturation, differences among ethnic groups in their perception of alcohol-related problems, the impact of sociocultural differences between patients and providers, and how prevailing social (e.g., family) relationships can affect treatment outcome.

**Conclusion**

During the past 30 years significant progress has been made in the scientific study of alcohol dependence and its treatment. On the basis of evidence reviewed in this chapter, a number of conclusions appear warranted at this time:

1. People with alcohol-related problems are heterogeneous with respect to demographic features (e.g., age, gender, race/ethnicity), age of onset of heavy drinking, severity of alcohol dependence, comorbid psychopathology, genetic vulnerability, and other prognostic factors.
2. The available evidence suggests that any treatment for alcohol dependence is better than no treatment. The majority of those treated demonstrate improvement, but many of these alcoholics may improve with minimal treatment.
3. The intensity of treatment has not been shown to produce pronounced differences in outcome (Moos and Moos 2003). Similarly, medical inpatient treatment, while more costly, is not demonstrably more effective than nonmedical residential or outpatient treatment. For patients with serious comorbid medical and psychiatric disorders, medical inpatient treatment may, nonetheless, be necessary. Some evidence indicates that continuing aftercare helps to maintain abstinence following short-term intensive rehabilitation in inpatient settings.
4. There is little evidence that any one treatment approach is superior. There is some support for certain kinds of behavior therapy and AA, but the effectiveness of disulfiram seems to depend on patient characteristics and compliance. Several kinds of carefully specified and theoretically derived therapeutic approaches show promise as a basis for a new generation of ambulatory treatments. These include the relapse prevention strategies that teach the alcoholic how to avoid high-risk relapse situations, and new pharmacologic agents (e.g., naltrexone) that appear to reduce the alcoholic’s risk of relapse by dampening the reinforcement potential of alcohol. Continued improvements in treatment outcome will depend upon successfully matching treatment settings and modalities to the specific needs of the individual patient.

National Institute of Mental Health (NIMH) (1990) Substance abuse comorbidity in schizophrenia. Bethesda, MD, USA.

Most mental health and medical professionals in the United States consider the psychostimulant cocaine as representative of the entire class of psychostimulant drugs. While far less literature exists regarding other psychostimulants, illicit abuse of substances such as methamphetamine and illicit use of prescribed substances such as methylphenidate (Ritalin) represent a growing health concern (Anglin et al. 2002). While the major abused psychostimulant in the United States is cocaine, this is not the case in several Western US cities, nor in the state of Hawaii (Rawson et al. 2002a). Worldwide abuse or regular use of amphetamines is more than double that of cocaine.

Consistent with the schema put forward by the DSM-IV-TR, this chapter defines the amphetamine-like substances to include the phenylisopropylamines amphetamine (AMPH), methamphetamine (METH), and phenylpropanolamine (PPA), the natural substances ephedrine and pseudoephedrine, and phenylethylamines including methylphenidate and pemoline. While METH and AMPH cause the vast majority of abuse and dependence, use of any of these substances has been associated with abuse and dependence, so as a class these will be referred to as amphetamine-type stimulants, or ATS, in this chapter.

By far, the most widely abused ATS is METH, which is commonly known as meth, speed, crank, CR, wire, and jib, and in its recrystallized smoked form, ice, crystal, or glass. Legitimate forms of METH prescribed for attention-deficit/hyperactivity disorder (ADHD) and weight control (Methedrine, Desoxyn, and Adipex) undoubtedly represent a miniscule source of the total amount abused each year. AMPH, most prevalent in Western Europe, is commonly known as amp, bennies, dex, or black beauties, and is prescribed as Adderall, Dexedrine, and Dextrostat in the treatment of ADHD, narcolepsy, weight control, and depression. Other agents that have been designated as Schedule II controlled substances by the Drug Enforcement Administration are methylphenidate (Ritalin, Concerta) and phenmetrazine (Preludin). Given the widespread prescription of Ritalin in the United States for ADHD and narcolepsy, its diversion to abuse appears rare (Kollins et al. 2002). On the street, Ritalin is known as Rits or Vitamin R. Pemoline (Cylert) is a Schedule IV agent, also used to treat ADHD and narcolepsy. A large number of Schedule III and IV phenylethylamines (benzphetamine, diethylpropion, mazindol, phenmetrazine, phenmetrazine, and phentermine) are used for weight control. There is no specific evidence that these substances represent a significant source of illicit diversion, and they are not further discussed in this chapter. ATS agents are also widely available in over-the-counter (OTC) preparations. As discussed below, PPA has been removed from the market, but ephedrine and pseudoephedrine are still very widely used as decongestants, and less so, phenylephrine and propylhexedrine (Gorelick and Cornish 2003). An excellent tabulation of currently available formulations of prescribed ATS agents is found in Greenhill et al. 2003.

Diversion of prescription medications for illicit use is not a major source of illicit precursor synthesis of METH or AMPH. Unfortunately, a large amount of stimulant abuse that is not easily quantified occurs at rave parties and other venues for experimentation (Poulin 2001). Drug use among such individuals probably represents substance misuse and is less likely to meet formal criteria for abuse. However, it is uncommon that those that go on to amphetamine dependence continue to supply their habit through licit sources. Further, medically appropriate use of synthetic stimulants does not appear to pose a significant risk for the induction of substance-use disorders. This has been most closely examined for the widely prescribed methylphenidate (Ritalin) for
ADHD; in this case, treatment may actually reduce the risk of developing substance abuse by controlling ADHD, itself a risk factor for substance abuse (Biederman et al. 1999). Further, methylphenidate poses a low risk for medical complications (Rappley 1997). With increasing distribution in the adult population, there may be concern that this picture may change (Levin et al. 1999). It has been postulated that the persistence of peripheral autonomic effects, as well as much longer half-life in the striatum, accounts for its low abuse potential relative to cocaine (Volkow et al. 1995, Volkow et al. 1999).

The socially acceptable and very desirable effects of prescribed ATS, weight loss and productivity enhancement, make widespread use, and thus abuse, unavoidable. Students and athletes appear particularly at risk for development of stimulant abuse, given that both exposure to licit and illicit sources and the pressures to use are high (Murray 1998, Teter et al. 2003). Of course, those whose jobs require sleep cycle reversal, long hours and so on, such as truck drivers, also appear at high risk (Akerstedt and Ficca 1997).

AMPH-like substances, especially METH, are most commonly injected or smoked by heavy users (Murray 1998). Its low melting point, similar to crack cocaine, makes it well suited as a smokable agent (Cho 1990). These routes provide the most rapid onset of action, though peak blood levels and half-lives are approximately the same as for the oral route (Cook et al. 1993, Lebish et al. 1970). Most likely, abuse by those experimenting with the agent is oral. Through the mid 1990s, the oral and intravenous routes were still the most popular (Hall and Hando 1993). Methylphenidate displays a significantly shorter half-life (2–4 hours) than AMPH and METH, reaching peak levels in 1–3 hours (Volkow et al. 1995). Methylphenidate abuse, however, is mainly through the intravenous route with crushed tablets (Parran and Jasinski 1991) though it may also be snorted (Garland 1998).

**Diagnosis**

Consistent with the DSM-IV-TR perspective functionally equating amphetamines with cocaine, those diagnostic categories that are included are identical to those for Cocaine-Related Disorders, with the sole exception of omitting the specifier “With Onset During Withdrawal” from the diagnostic category Amphetamine-Induced Anxiety Disorder. For the substance use disorders, amphetamine (ATS) abuse and dependence will be discussed below. Of the substance-induced disorders, the critical diagnoses of ATS intoxication and withdrawal are described. The specific complications of delirium, psychotic disorders, mood disorders, anxiety disorders, sexual dysfunctions, and sleep disorders all are described under intoxication. Amphetamine-induced mood and sleep disorders also allow for specifiers of onset during withdrawal.

**Amphetamine Dependence**

ATS dependence is diagnosed when a maladaptive pattern of use leads to clinically significant impairment or distress, as defined by three or more of the following that occur during the same 12-month period: (1) evidence of tolerance, (2) occurrence of withdrawal, or the reuse of the substance to alleviate withdrawal, and (3) compulsive use of amphetamines as defined by three or more of the following: using more than intended, (4) desire or efforts to reduce use, (5) occupying significant time in drug-related activities, (6) loss of social, occupational, or recreational pursuits, or (7) continued use despite known adverse, physical, or psychological consequences.

**Amphetamine Abuse**

The diagnosis of ATS abuse requires a maladaptive pattern of use that does not meet the criteria for dependence, and that results in clinically significant impairment or distress. In the preceding 12 months, recurrent substance use must result in one or more of the following: failure to meet major role obligations, placement of the user in physical danger, legal entanglements, or social/interpersonal problems.

**Amphetamine Intoxication**

Specific diagnostic criteria are provided for ATS intoxication (see DSM-IV-TR diagnostic criteria below). These include recent use of an ATS (criterion A), clinically significant maladaptive behavioral or psychological changes.

---

**DSM-IV-TR Criteria 292.89**

**Amphetamine Intoxication**

A. Recent use of amphetamine or a related substance (e.g., methylphenidate).

B. Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity; anxiety, tension, or anger; stereotyped behaviors; impaired judgment; or impaired social or occupational functioning) that developed during, or shortly after, use of amphetamine or a related substance.

C. Two (or more) of the following, developing during, or shortly after, use of amphetamine or a related substance:

1. tachycardia or bradycardia
2. pupillary dilation
3. elevated or lowered blood pressure
4. perspiration or chills
5. nausea or vomiting
6. evidence of weight loss
7. psychomotor agitation or retardation
8. muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
9. confusion, seizures, dyskinesias, dystonias, or coma

D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

Specify if:

**With Perceptual Disturbances.**
use of PPA also is associated with psychosis (Goodhue et al. 2000, Norvenius et al. 1979). Women appear to be at greater risk, as do those with preexisting mood or psychotic disorders (Marshall and Douglas 1994).

The physiological disturbances in criterion C are listed in Table 55–2, again with author’s comments in parentheses.

### Amphetamine Withdrawal

While the intoxicated state is characterized as euphoric, expansive, and activated, and often presents with agitation, violence, and/or psychosis, ATS withdrawal is characterized by decreased energy and mood. The clinician often evaluates such individuals who become suicidal during cessation of (or reduction in) amphetamine (or a related substance) use that has been heavy and prolonged.

**B.** Dysphoric mood and two (or more) of the following physiological changes, developing within a few hours to several days after Criterion A:

1. fatigue
2. vivid, unpleasant dreams
3. insomnia or hypersomnia
4. increased appetite
5. psychomotor retardation or agitation

**C.** The symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

**D.** The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

---

the “crash.” The period of most intense withdrawal may last days, though a protracted state of depression and low energy often persists for weeks (Kramer et al. 1967, Murray 1998). Resurgence of craving when exposed to drug-associated environmental cues probably persists for years, as is the case with other substance-dependence disorders. The occurrence of ATS withdrawal usually occurs in those that have progressed from the diagnosis of abuse to dependence.

The ATS withdrawal diagnosis requires cessation or reduction of ATS use that has been heavy or prolonged (criterion A), dysphoric mood and at least two physiologic changes that occur from a few hours to days after cessation of use (i.e., fatigue; vivid, unpleasant dreams; insomnia and hypersomnia; increased appetite; psychomotor retardation or agitation) which cause clinically significant distress or impairment in social, occupational, or other important areas of functioning (criteria B and C); and the requirement that the condition is not accounted for by another mental or medical condition (criterion D) (see DSM-IV-TR diagnostic criteria above).

Both the longer half-lives of ATS relative to other psychostimulants, as well as the broader-spectrum effects on nerve terminal catecholamine levels, result in prolonged withdrawal and abstinence states. ATS withdrawal states occur in some 87% of users (Cantwell and McBride 1998, Schuckit et al. 1999). The acute phase appears to last up to 5 days, with some symptoms persisting for weeks, possibly months, following the acute phase (Srisurapanont et al. 2001a, Watson et al. 1972).

Since neurocognitive impairment occurs early in withdrawal, clinicians should be cognizant that instructions to individuals in withdrawal be kept simple and written out (Karch 2002). Decision making, as has been known anecdotally for years, appears affected (Paulus et al. 2003). If individuals with amphetamine dependence fail to appear in follow-up, outreach attempts are necessary to keep the individuals engaged. EEG data support alterations during early withdrawal (Newton et al. 2003). Over months, these cognitive deficits may partially remit to a greater extent than in opiate abusers (Rogers et al. 1999, Ornstein et al. 2000). Severe craving marks the early withdrawal phase, leading to high recidivism. Sleep disturbance is accompanied by increase in REM sleep (Watson et al. 1972).

**Epidemiology**

After cannabis, worldwide ATS (principally METH and AMPH) are regularly used or abused by some 35 million individuals (United Nations Drug Control Program 2003). In contrast, cocaine is used by 15 million worldwide, and heroin by 10 million. The United Nations Office of Drug Control Report (2003) showed that, except for cannabis, more new countries reported use of ATS than any other illicit substance. Interestingly, while cocaine is the most widely used psychostimulant in the Americas, outside of these areas, especially in the Far East and Southeast Asia, Oceana, and Western Europe, ATS abuse is far more prevalent (United Nations Drug Control Program 2003). It is estimated that two-thirds of the world’s ATS abusers live in Asia, with Thailand experiencing perhaps the most severe epidemic (Ahmad 2003). The long half-life and relatively inexpensive nature (approximately 25% the cost of use of cocaine) make it possible to continue use for years without adverse sequelae necessitating treatment or incarceration. (Simons et al. 2002b). However, it seems likely that users in the workplace may suffer increased use of other health care services, loss of workplace attendance and so on.

It is estimated that 5–10% of adults have a lifetime prevalence of nonprescription ATS use. 0.5% in the last year, and 0.2% in the prior month (SAMHSA 2003). Roughly, 5% of adults in the United States have had a history of nonprescribed use of ATS drugs, 1% in the prior year, and 0.4% in the prior month. ATS dependence and abuse combined have approximately a 1.5% lifetime prevalence according to DSM-IV-TR. The performance-enhancing effects of ATS place students faced with competitive stress such as high-achievers and athletes at high risk (Bailey 1987, Conrad et al. 1988). Since performance enhancement is much more pronounced under conditions of sleep deprivation, abuse by those in repetitive, sleep-shifted occupations, such as truck drivers, is also high (Heishman 1998).

The prevalence of ATS use appears particularly related to supply routes, perhaps because its sole source of production is synthetic, and not grown. While originally diverted from pharmaceutical supplies (such as via the US armed forces into Japan in the 1950s), and synthesized by biker gangs, it is now produced by a more wide variety of small producers, as well as “superlabs” producing 10–100 lb batches in Mexico where precursor supplies are not legislatively limited (Karch 2002). Small production sites are likely to remain because its synthesis is relatively easy, and provides for personal use as well as excellent profit margins. Further, precursor supply interdiction appears to affect large producers to a far greater extent than the small backyard labs (Cunningham and Liu 2003).

METH is the predominant form of ATS used in the world today. This is especially true in the United States west of the Mississippi, in Hawaii, Taiwan, Japan, and Southeast Asia (Rawson et al. 2002a). METH-related emergency room admissions represent a small but rapidly growing problem in these regions (Karch 2002). The demographics of METH use are also unusual for the United States. METH use, as well as deaths related to METH use, is predominantly male (86%) and Caucasian (75%), as well as surprisingly old (mean 36.8 years of age) (Karch 2002). Use in the last several years appears to be spreading beyond the typical unemployed, single Caucasian males that originally characterized users during past epidemics (Baberg et al. 1996).

The clandestine nature of production in small “mom and pop” labs, and the release of easily detected noxious fumes, makes rural production, and thus rural use, a particular problem. These demographics present problems for smaller health-treatment resources ill equipped to handle mental health issues integrally linked to antisocial and violent behavior.

**Patterns and Routes of Use**

ATS is regarded as highly addictive, with some 50% who initially experiment illicitly with ATSs progressing to dependence (Woody et al. 1993). Heavy users, especially of METH, most commonly inject or smoke. These routes appear to have the highest potential to result in dependence (Gorelick and Cornish 2003). Its low melting point, similar to crack cocaine, makes it well suited as a smokable substance. Most likely, abuse by those experimenting with the agent is
oral. Indeed, even OTC preparations containing ephedrine and pseudoephedrine are commonly abused (Tinsley and Watkins 1998). Through the mid 1990s the oral route, and intravenous, were still the most popular (Hall and Hando 1993). Methylphenidate abuse, however, is mainly through IV route with crushed tablets (Parran and Jasinski 1991), though it may also be snorted (Garland 1998).

It is believed that ATS smoking and IV abuse lead to more rapid dependence than oral and snorted abuse. By the smoking route METH reach the brain in seconds, and the initial “rush” occurs soon thereafter, with peak effects at 2–4 minutes. Intravenously, ATS probably peak slightly later, though this conclusion is based on the extension of studies with cocaine (Telang et al. 1999).

There are two main patterns of heavy use—binge use and chronic use. In binge use (“speed runs”), increasing amounts are used over a few days, usually ended by exhaustion of resources, the user, or the onset of adverse events, such as intense agitation or psychosis. The second pattern of use in dependent individuals is chronic, repeated use over long periods. This pattern is sustained both by IV and smoking routes, as well as oral use.

Methylphenidate is believed to be less addictive than other ATS for several reasons. It appears to be cleared from human brain sites far more slowly than cocaine (Volkow et al. 1995) and so should show a reduced addictive potential. Further, it appears to cause less euphoria than AMPH (Klein and Wender 1995). In the main, ATS taken by the oral route reach maximum plasma level in 1–3 hours, but half-life of effect is more varied. Methylphenidate, PPA, and phenylephrine have half-lives of 2 to 2.5 hours, significantly shorter than those for AMPH (7–34 hours) and METH (6–15 hours) (Baselt 1999).

As with other stimulants, adverse subjective effects experienced by users may be tempered by co-use of depressants, including alcohol and benzodiazepines, but there are no large studies of such comorbidity.

METH is cleared from the body by several routes. Approximately 45% is excreted unchanged in the urine, though this can be increased by acidification of the urine (Cook et al. 1993, Wan et al. 1978); conversely, ingestion of sodium bicarbonate can reduce elimination and concentrations in the urine (to hinder detection) (Braithwaite et al. 1995). Approximately 20% is N-demethylated to form AMPH (Caldwell et al. 1972). This fact is used to advantage in distinguishing METH positive urines that result artifically from current analytic processes with ephedrine testing (where no AMPH is found) to positives where both METH and AMPH are present (supporting actual METH use). These compounds undergo further metabolism via oxidation (forming norephedrine and other active metabolites), parahydroxylation (also to active compounds), and deamination (to inactive products). All phenylisopropylamines competitively inhibit CYP2D6 (Wu et al. 1997).

**Medical Complications**

For heavy users, a number of general consequences of ATS dependence will be obvious; malnutrition and cachexia from sleep deprivation, exposure to the elements and so on. Skin disorders, including infections and lesions from “picking” are common. More serious are ATS-related deaths due to cardiac arrhythmias, stroke, and rhabdomyolysis that have been documented since the 1950s. These problems were similar to those reported for the more widely abused cocaine. Concern over unique toxicity further increased when “ice,” the smokable form of METH, began to be seen in Japan in the late 1970s (Cho and Wright 1978). Still there is only approximately 1 METH-related death for every 10 related to cocaine, and the reasons that may be are described below. Also as described below, a number of factors place ATS users at high risk for contraction of HIV, and likely Hepatitis B and C, infection.

Some of the medical complications result from exposure to contaminants during ATS use. The production methods for ATS determine what contaminants are present in illicit manufacture. Contaminants are both toxic, as well as stimulants in their own right (Soine 1986). In the United States, the “red phosphorous” route of conversion of (−) ephedrine (to METH) and (+) pseudoephedrine (to DEX) is nearly exclusive today. Contaminants such as 2-phenylethyl-phénylèthylamine are common to both processes. Now that it is recognized that ephedrine is being illicitly diverted in the United States, its importation is also being regulated. METH cooks occasionally resort to other cold remedies and stimulants, but these appear to represent minor supply sources, for example, substitution of phenylpropanolamine (PPA) leads to production of DEX.

For methylphenidate, the principal complications occur only when the drug is diverted to illicit intravenous use. Its formulation makes talscosis resulting from IV use prominent, where the lungs (Schmidt et al. 1991) and eyes (Lederer and Sabates 1982) are most affected. There are case reports of catecholamine toxicity with intentional overdose, and the complication pattern is not unique compared to METH.

Many of the cardiovascular complications for ATS described below result from peripheral catecholamine toxicity. This explains why the principal drug interactions of concern involve the psychotropics that are meant to augment catecholamine function. Of most concern are the monoamine oxidase inhibitors, whose action can potentiate ATS toxicity for 2–3 weeks following cessation of use. Similarly, tricyclic antidepressants can potentiate effects of ATS, as well as increase absorption and slow hepatic metabolism (Gorelick and Cornish 2003). However, off-label use of ATS to augment tricyclics is not uncommon, and at least one study has found that desipramine and stimulants (i.e., methylphenidate and dexameth) have no clinically significant interaction in children (Cohen et al. 1999).

**HIV and Immunomodulatory Effects**

It is now appreciated that intravenous drug use is the fastest growing route for transmission of HIV infection (NIDA Research Report, 2002). In addition, ATS use is associated with unsafe sexual behaviors, including participation in unprotected sex and involvement with multiple sexual partners (Molitor et al. 1998, Chesney et al. 1998, Zule and Desmond 1999). This results from the drug’s acute effect of enhancing libido and impairing judgment, and from the association of ATS use with sexual behavior among gays (Shoptaw et al. 2002). In the Shoptaw study, two-thirds of treatment-seeking ATS users were HIV positive. Once HIV has been contracted, ATS abuse leads to accelerated CNS and cardiovascular toxicity (Nath et al. 2001, Yu et al. 2003). METH and AMPH are immunomodulators, and in fact,
may be immunotoxic to peripheral T cells, mitogen-stimulated lymphocytes, and spleen cells (Yu et al. 2003). METH use and HIV infection may synergistically interact to accelerate the course of the HIV infection (Phillips et al. 2000).

**Pulmonary**

In the Karch autopsy series (1999) of individuals who died from ATS use, pulmonary edema was present in 70% of cases, as well as pneumonia (8.2%), and emphysema (5.1%). Birefringent crystals at bifurcation of pulmonary vessels is associated with intravenous abuse of crushed pills that contain insoluble fillers such as talc, microcrystalline cellulose, corn starch, or cotton fibers. With sufficient deposition, small vessel thrombosis and granuloma formation ensues (Tomasheski and Hirsch 1980). The changes ultimately reduce pulmonary perfusion, and increase pulmonary vascular resistance (Kringholm and Christoffersen 1987). Possibly because of an increased ratio of intravenous drug abuse to other routes, heroin abusers are more prone to progress to pulmonary thromboembolic complications than are stimulant abusers. Less commonly, oral tablet consumption by the IV route results in pulmonary amyloid formation (Shah et al. 1998).

**Gastrointestinal**

In METH-related deaths, the sum of liver-related complications was second highest among organ systems. Fatty liver (16.2%), cirrhosis (9.0%), portal triaditis (6.1%), and hepatitis (4.1%) were detected (Karch et al. 1999b). This may relate to the high comorbidity with alcohol dependence, though the exact contribution is unknown. One pathophysiological connection may be hepatotoxicity secondary to excessive alpha2-adrenergic stimulation (Roberts et al. 1997). ATS, including pemoline (Cylert) and methylphenidate (Ritalin) have been specifically implicated as hepatotoxins, though this appears to be rare, idiosyncratic hepatocellular damage (Nehra et al. 1990, Mehta et al. 1984).

**Cardiovascular**

Both cocaine and ATS cause similar vascular toxicity, largely related to catecholamine excess (Todd et al. 1985a, b). Hearts of stimulant abusers develop areas of fibrosis and contraction band necrosis, and usually are increased in weight. Typically, interstitial fibrosis with myocyte hypertrophy is found at autopsy (Karch 2002). As well, coronary artery disease is accelerated. At autopsy, 16.4% of METH-related deaths showed moderate to severe coronary artery disease (Karch et al. 1999b). Aortic dissection is a less well known but catastrophic complication of METH use (Swalwell and Davis 1999). Yu et al. (2003) also argue that immunosuppressive effects of ATS lead to enhanced cardiotoxicity. Cardiotoxic effects are partly reversible (Islam et al. 1995).

Case reports of myocardial infarction that occurs following ATS are known for use by any route (Furst et al. 1990 Packe et al. 1990, Derreza et al. 1997). Limited data indicate that infarctions result from coronary spasm rather than the results of fixed lesions. Why are myocardial infarction rates with METH so much less than those with cocaine? Karch hypothesizes that the prolonged nature of insult required to damage the fairly hardy cardiovascular system is more the exception than the rule in human users; many more people experiment with ATS than become regular users. Further, hyperthermia, more common with METH than cocaine results in the production of heat shock proteins that may be protective of ischemic damage (Maulik et al. 1995). Cardiomyopathy also appears more rarely in METH use than for cocaine (Smith et al. 1976, Call et al. 1982, Jacobs 1989).

The phenomenon clearly occurs at increased rates relative to controls with METH (Matoba et al. 1986, Hong et al. 1991). While most ATS seem similar, methylphenidate may produce a unique pattern of lamellated ultrastructural lesions in the heart (Henderson and Fischer 1995). Of note, heart failure in children treated with Ritalin is so rare as to be at the case report level.

**Central Nervous System**

As opposed to the medical complications described above, which often are discerned at autopsy, CNS effects including psychosis and stroke are common presenting symptoms in emergency departments.

Seizures are one of the most common presentations of ATS intoxication to emergency rooms (Alldredge et al. 1989). In association with an uncontrollable delirium, they can quickly lead to death if not controlled. Following decreases in ATS blood levels, individuals who abuse ATS are not left at increased risk for reoccurrence of seizures unless CNS lesions from prior stroke have developed.

Strokes associated with ATS can be ischemic or hemorrhagic in nature. These are seen with METH that is taken IV (Imanse and Vanneste 1990, Yen et al. 1994, O’Brien 1998, Pettiti et al. 1998), smoked (Rothrock et al. 1988, Yen et al. 1994), or taken orally (Delaney and Estes 1980). Intracerebral hemorrhage, or a combination of intracerebral and subarachnoid hemorrhage, appear to be the most common stroke type (Harrington et al. 1983). Similar to cocaine, the frontal lobes are most commonly involved, followed by the basal ganglia. These are the same areas where dopamine depletion appears to be the most prominent, and differs from the areas of highest involvement with hypertensive hemorrhagic stroke, where the basal ganglia and hypothalamus are most commonly involved.

The alleged connection between hemorrhagic stroke and phenylpropanolamine (PPA; ±norephedrine) prompted its withdrawal from the market in 2000 (Kernan et al. 2000). Widely used in cold and cough remedies, it was also popular as an appetite suppressant. Compared to METH and AMPH, it has much higher affinity for alpha-adrenergic receptors than beta. Thus, the agent has greater affects on peripheral blood pressure. However, its overall pattern of toxicity is again consistent with catecholamine excess, though cerebral vasculature seems more affected than coronary or pulmonary vessels (Karch 2002).

Ischemic stroke most commonly follows embolism (Pettiti et al. 1998). In some cases, this appears related to an intimal fibrinoid necrosis and mixed cellular infiltrates that results in luminal compromise (Cifron et al. 1970, Stafford et al. 1975, Bostwick 1981). A number of oral agents, including methylphenidate and ephedrine, have been implicated in vasculitis (Trugman 1988, Scheinshnader et al. 2000).

Hyperthermia is related to a number of causes in those presenting with METH intoxication. Increased motor activity, with reduced heat dissipation from peripheral vasoconstriction is the proximate cause. It is also likely that direct affects on hypothalamic thermal regulation exist.
In humans, METH use is correlated over time with declines in N-acetylaspartate levels in basal ganglia and frontal white matter (Ernst et al. 2000, Nordahl et al. 2001). These changes, however, are not correlated with gross histopathologic changes in METH-related deaths. A clue that dopamine declines might be related to functional incapacities, however, is the fact that hyperthermic crises during METH use appear to be related to basal ganglia depletion of dopamine (DA) (Bowyer et al. 1994).

Renal
Rhabdomyolysis is clearly the major concern for renal impairment; there does not appear to be independent toxicity to the kidney (Karch 2002). However, METH is an increasingly common cause of rhabdomyolysis (Richards et al. 1999), and is often associated with hyperthermia. Myoglobin and myoglobin breakdown products cause tubular obstruction. Renal damage results from hypotension and renal ischemia secondary to metabolic derangements secondary to rhabdomyolysis, including phosphorus and potassium imbalance, and tubular obstruction due to catabolic product accumulation.

Effects on the Fetus
Fetal loss, developmental delay, and subsequent learning disabilities are potential complications of ATS use during pregnancy. While widely quoted, it appears that perinatal complications may be more rare than expected (Catanzarite and Stein 1985, also see Plessinger and Woods 1998). This is despite the fact that fetal exposure is widespread (Oro and Dixon 1987). Karch puts forward the argument that the about-to-be-born fetus is protected from AMPH-related toxicity because it has already been prepared for the catecholamine surge that occurs during childbirth by down-regulation of catecholergic receptors. Preclinical studies indicate METH also concentrates in the fetus (Stek et al. 1993), supported by a limited number of human autopsy cases (Stewart and Meeker 1997). In reported cases, fetal death was not attributable to drug presence; conversely pregnancy may increase the risk of METH use (more common than cocaine) (Vega et al. 1993). METH also concentrates in breast milk (Steiner et al. 1984), but ill effects on children remain controversial (Briggs et al. 1975, Eriksson et al. 1978, Little et al. 1988a, b; Joffé and Kasnic 1994). Most recent studies support a small effect of newborn birthweight, and a low incidence (4%) of overt ATS withdrawal in newborns of METH-dependent mothers (Smith et al. 2003).

Etiology
ATS operate as indirect sympathomimetics to enhance catecholamine release, and at higher doses, serotonin release. Practically speaking, these agents increase peripheral norepinephrine (NE) levels in the sympathetic nervous system, and centrally, dopamine, norepinephrine, and serotonin levels. Release of central dopamine appears to be the primary action mediating the addictive potential of ATS, but release of NE mediates many of the toxic and peripheral effects (Wilens and Spencer 1998, Sevarino et al. 2000). Postsynaptically, the principal peripheral effects are to stimulate alpha and beta adrenergic receptors. In virtually all actions, the D-stereoenantiomer of the compounds at their alpha-carbon center is 3–5 times more active than the l-enantiomer (Gorelick and Cornish 2003). The precise mechanisms by which these agents affect synaptic levels of neurotransmitters is best understood for AMPH, METH, and methylphenidate.

Acute there are four identified molecular targets of AMPH. In the dopamine system, AMPH acts as a false substrate for the dopamine transporter (DAT) (Amara and Sonders 1998). This transporter is the principal exchange mechanism by which released dopamine (DA) is cleared from the synapse and recycled into the synaptic nerve terminals. Elegant studies have now determined that AMPH results in elevation of intracellular sodium, causing the kinetics of DA exchange through the DAT to favor outward movement of DA (Khoshbooei et al. 2003, Jones et al. 1999). AMPH is internalized where it enhances release of vesicular stores of DA (and NE) into the cytoplasm where exchange via the DAT occurs. This appears to be through inhibition of vesicular monoamine transporter (VMAT)(Boja and Meil 1998), an action shared by cocaine (Brown et al. 2001). VMAT partial knockout mice show enhanced locomotor stimulation by AMPH, reduced reward, and absent sensitization (Uhl et al. 2000). AMPH is selective for releasing newly synthesized cytoplasmic catecholamine stores before enhancing vesicular release; methylphenidate acts more on vesicular pools (Greenhill et al. 2003). A key difference appears to be AMPH’s selectivity for action at the DAT, and not on vesicular transport or cytoplasmic DA release (Seidler et al. 1993, Volkow et al. 1995). Third, AMPH inhibits the DA degradative enzyme catechol-O-methyltransferase (COMT), which would sustain extracellular levels of dopamine. Finally, intracellular monoamine oxidase A is inhibited, an action not found for cocaine. This last action would raise levels of both DA and NE, but it is unclear if levels reached in vivo would achieve this effect (Rothman et al. 2001). A prominent difference between cocaine and ATS agents is the lack of sodium transporter inhibition by the latter (Hoffman and Lefkowitz 1990).

ATS has similar effects on the NE system. In fact, ATS may be more potent at releasing NE centrally than DA (Rothman et al. 2001). Both AMPH and METH appear to affect both the DAT and NET, while methylphenidate is more selective for the DAT (Giros et al. 1996). Whether this relates to the abuse-liability hierarchy, where both METH and AMPH appear more addictive than methylphenidate, is unknown (Langer et al. 1986). Norepinephrine transporter (NET) knockout mice are hypersensitive to the locomotor stimulating effects of AMPH (Xu et al. 2000). Serotonin system effects of ATS are even less well understood, though the serotonin transporter (5HTT) is also antagonized by ATS.

The neuroanatomical substrates of ATS agents are also being characterized. By virtue of their lipophilicity, these agents easily cross the blood-brain barrier and show selective accumulation in various brain loci. In particular, the striatum is an area of accumulation for methylphenidate (Volkow et al. 1995). The neostriatum (caudatoputamen and nucleus accumbens) is particularly activated by ATS agents, as well as projections to the orbitofrontal regions and other limbic areas. The neocortex appears inhibited. In more primitive areas of the brain, the ascending reticular activating system and medullary respiratory centers are activated.
A rich literature exists in animal studies supporting the development of neurobiological adaptations to chronic ATS exposure. In humans, the development of tolerance to acute effects such as euphoria and anorexia, the persistent potential for relapse once one has become addicted, and the ability to reexperience psychotic symptoms with low doses of ATS exposure long after chronic use, support long-term changes in humans as well (Sato et al. 1983, 1992, Wilens and Spencer 1998). Sensitization to amphetamines can be demonstrated with eye blink in humans (Strakowski et al. 2001) but only if subjects have not had prior exposure to amphetamines (Comer et al. 2001). This would argue that at least to this marker, sensitization is achieved quickly. Tolerance to ATS also can develop after only several exposures (Gorelick and Cornish 2003).

The DA depletion hypothesis has long been used to explain the long-term effects of psychostimulant abuse (Dackis and Gold 1985). In animals, METH and AMPH dose-dependently reduce the activity of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine synthesis, and DA levels in the nerve terminals decline (Koda and Gibb 1973). AMPH seems to be less neurotoxic than METH in these models (Ellison and Switzer 1993). Nonetheless, DA recovery in rat striatum is remarkably slow, taking months, more consistent with neuroadaptations such as neuronal sprouting rather than resynthesis of depleted stores (Cass and Manning 1999).

The issue of whether DA is depleted in chronic users is critical to understanding imaging findings in chronic METH-dependent individuals that support long-term changes in the DAT. Reductions in DAT can be demonstrated in the caudate and putamen (Wilson et al. 1996, McCann et al. 1998, Volkow et al. 2001a). These reductions correlated with motor and cognitive impairments, and were present in users abstinent for over 11 months. While animal studies support nerve terminal degeneration with high-dose METH administration, in humans it appears other neuronal markers, for example VAMT, are still present, and recovery may be possible over a period of years (Wilson et al. 1996, Volkow et al. 2001b). Sekine and colleagues have demonstrated that DAT reductions are also prominent after chronic METH use in the orbitofrontal and dorsolateral prefrontal cortices, the amygdala, and the nucleus accumbens (Sekine et al. 2001, 2003). Except for the amygdala, these reductions correlated with length of use, and the positive subscale of the Brief Psychiatric Rating Scale. The fact that dopamine D2 receptor function is reduced in the striatum may explain orbitofrontal dysfunction (Volkow et al. 2001c). These findings clearly support long-term alterations caused by METH, but it is unclear why DAT levels would be reduced in the presence of depleted DA levels. There are limited data that oxidative products of DA might specifically inactivate the DAT (Cho and Meleaga 2002, Hastings et al. 1996, Bindoli et al. 1992).

METH also is neurotoxic to striatal serotonin nerve terminals, again inducing long-term changes in animals (Cass 2000). At high doses, METH appears to permanently destroy serotonin nerve terminals (Woolverton et al. 1989). Surprisingly, little is known about the effects of acute or chronic ATS exposure on the NET.

Preclinical studies also support the importance of glutamatergic transmission in modulating dopaminergic areas, and in turn affecting the development of sensitization to psychostimulants (Vanderschuren and Kalivas 2000). Animal studies (Zhang et al. 2001) show METH and cocaine do not acutely elevate the glutamate in the striatum or nucleus accumbens. After chronic exposure, rechallenge with METH increased caudate glutamate and decreased nucleus accumbens glutamate, while cocaine increased glutamate in both regions. Acute METH decreased glutamate in substantia nigra and ventral tegmentum, while cocaine increased glutamate in the same regions. Thus, glutamate effects remain to be discerned, but support important differences between cocaine and ATS. Kalivas and colleagues (Pierce and Kalivas 1997) hypothesize that chronic AMPH exposure will recruit glutamatergic cortical inputs to the nucleus accumbens, mirroring environment cue association with drug reward. Further, glutamate antagonists block the development of locomotor sensitization to stimulants (Vanderschuren and Kalivas 2000).

While the long-term adaptations to ATS and cocaine are usually held to be similar, the bulk of studies have been with cocaine only (White and Kalivas 1998, Robinson and Berridge 2000). Cross sensitization between cocaine and AMPH can be demonstrated (Bonate et al. 1997). However, given the differing pharmacology of cocaine and ATS, it is not surprising that evidence does exist that long-term processes such as sensitization can vary between cocaine, AMPH, and methylphenidate (Vanderschuren and Kalivas 2000).

**Treatment**

There are few studies that specifically address the treatment of ATS use disorders. This reflects the traditional focus on cocaine use disorders. Even for cocaine, effective pharma-cotherapies are lacking compared to treatment of alcohol- and opiate-dependent individuals. Behavioral treatment approaches remain the mainstay of treatment of psychostimulant use disorders, and those whose efficacy is supported in the cocaine use disorders are assumed will be effective for ATS use disorders. Outcomes in psychosocial treatment cohorts do appear to be similar (Huber et al. 1997, Rawson et al. 2000).

Several unique aspects of ATS addiction must be addressed for treatment to be effective. Because ATS users begin to experience adverse consequences of their use later than comparable cocaine addicts, they appear to be more ambivalent to enter treatment, probably because they reason that since they have gotten along fairly well up to that point, why should they begin the difficult process of treatment? Thus, treatment entry and retention rates are lower than those for individuals with cocaine dependence, and necessitates outreach programs to enhance treatment engagement (Huber et al. 1997). A number of co-occurring problems, such as high HIV and hepatitis infection rates, homelessness, and child-rearing difficulties must be integrated into the treatment approach. Further, the continued neurocognitive deficits in METH-dependent individuals increase the need to apply outreach attempts to noncompliant individuals (Simon et al. 2000a).

Association with difficult-to-alter behaviors (sexual/social and weight loss) means those “rewards” must be coopted by substitution of other options, such as referral to self-help groups for weight loss. As for any addiction, the
need to separate reinforcing social contacts from the addict’s lifestyle is a difficult process. Abuse by those seeking performance enhancement may be targeted through education programs and drug screening programs, such as those that have been so successful in the military (Rawson et al. 2002a).

**Treatment of ATS Intoxication**

Management of acute intoxication is guided by the presenting medical and psychiatric symptoms. In ATS intoxication, there are no direct receptor targets to achieve blockade; though dopamine receptor blockade theoretically should be useful in blocking acute and or chronic affects of ATS, this has not proven to be the case (Sevarino et al. 2000). Anxiety and agitation are first treated by an environment that reduces stimulation and provides orientation, with staff providing reassurance and talk downs (Khantzian and McKenna 1979). Physical restraints should be avoided, as these may worsen rhabdomyolysis or hyperthermia. When nonpharmacological means are insufficient, benzodiazepines, typically lorazepam or diazepam, are first-line treatments since they protect against imminent seizures. Antipsychotics for agitation should be avoided because of the risk of worsening hyperthermia or rhabdomyolysis if neuroleptic malignant syndrome were to occur, and their ability to lower seizure threshold. However, since benzodiazepines run the risk of disinhibiting some individuals, typical antipsychotics are often the preferred choice. Indeed, in one controlled trial, intravenous droperidol was significantly faster than intravenous lorazepam in sedating ATS-intoxicated psychotic individuals (Richards 1997, 1998).

For psychosis and paranoia, high potency antipsychotics, typically haloperidol, are used. This avoids the anticholinergic effects that may worsen delirium and hyperthermia. There is no reason to assume that atypical antipsychotics, such as intramuscular ziprasidone, might not be effective in this population, though there are no trials examining this. While there are no controlled trials on the treatment of ATS-induced psychosis (Srisurapanant et al. 2001c), it appears the psychotic symptoms do not differ from those in schizophrenia in their response to acute intramuscular injection of typical neuroleptics (Angrist 1974). While preclinical literature would argue that DA or serotonin blockade should block the acute subjective effects of ATS use, clinical evidence has not supported this (Wuchtel et al. 2002).

The management of medical sequelae of ATS intoxication, most commonly nontraumatic chest pain, is well described in Wilkins et al. (2003). If oral use of the ATS is suspected or confirmed, charcoal gastric lavage is indicated. Acidification of the urine with ammonium chloride solution or cranberry juice may be used to enhance ATS excretion, though should be avoided if rhabdomyolysis is a concern, since this would worsen dissociation and precipitation of myoglobin (Karch 2002), or where renal or hepatic dysfunction are an issue (Hurbut 1991). Basic life support and initial management are needed for critical conditions such as myocardial ischemia or arrhythmia, stroke or seizures, hyperthermia and rhabdomyolysis. Hypertension and tachycardia, if not responsive to benzodiazepine sedation, may require treatment with an alpha-adrenergic blocker, typically phentolamine. Agents with beta blockade activity, such as propanolol and labetolol, must be avoided as alpha-adrenergic tone can increase, leading to a worsening of the clinical condition (Ramoska and Sacchetti 1985).

**Treatment of ATS Withdrawal**

Emergency considerations in the withdrawal phase of ATS intoxication are principally psychiatric. The week following cocaine withdrawal is associated with increased risk of silent myocardial ischemia (Nademane et al. 1989). Because this is hypothesized to result from coronary vasospasm, this may not generalize to ATS withdrawal. Otherwise, medical complications of ATS withdrawal, such as myalgias, involuntary motor movements and so on can be treated symptomatically and should spontaneously remit.

The use of antidepressants for 3–4 weeks following cessation of ATS use is suggested, because depression is a hallmark of ATS withdrawal (Watson et al. 1972, Ellinwood 1975). Often, allowing the individual increased time to sleep and reestablishment of normal nutrition is quite helpful. Where needed, the use of trazodone for sleep or short-term benzodiazepines for anxiety is needed along with antidepressant therapy.

**Psychosocial Treatments for ATS Dependence**

Cognitive behavioral therapy forms the basis of many treatments for psychostimulant dependence (NIDA Research Report 2002). NIDA-sponsored treatment efforts mainly have focused on those with cocaine dependence, but there is no reason to assume that these approaches cannot form the basis of treatment for ATS use disorders. Contingency incentives, skills training, and family member participation are helpful for maintaining cocaine abstinence (Higgins et al. 1993). An extension of such a combined approach, termed the community-reinforcement-plus-vouchers approach, is described in the Treatment Improvement Protocol Series (TIPS) 33: Treatment for Stimulant Use Disorders (CSAT 1999). This approach combines couples counseling, vocational training and skills training (community reinforcement, see Meyers and Smith 1995), and contingency management through rewards for negative urine testing. This combined approach for treatment of cocaine dependence is shown to improve treatment retention and decrease drug use (Higgins et al. 1993, 1994). Further, the approach has been manualized to improve consistency among clinicians (Budney and Higgins 1998).

Contingency management by itself is likely to improve outcomes in ATS use disorders (Sitzer and Higgins 1995, Petry and Martin 2002). Besides rewards for negative urines, more general targets such as improved compliance with treatment, improved employment efforts, and decreased legal involvement can be utilized to more broadly impact the consequences of ATS use. In fact, the drug court approach (i.e., an alternative corrections system that routes addicts to the “drug court” rather than the traditional court system) may be particularly applicable to stimulant dependence because it is so concretely consequence based (Rawson et al. 2002a). Coordination between mental health services, social services resources, and the criminal justice system will be critical in reducing overall ATS use (Rawson et al. 2002a).

The manualized Matrix Model is a second integrated treatment approach utilized in southern California
for ATS-dependent individuals (Rawson et al. 1990). This combined approach of group and individual counseling, along with encouragement to participate in 12-step programs, incorporates elements of drug counseling, psychoeducation, motivational enhancement, relapse prevention (see below), family involvement, and case management. The Matrix approach is associated with large reductions in METH use, a decrease in high-risk sexual behavior, improved employment status, and reduced paranoia, though problems with depression persist (Shoptaw et al. 1994, Huber et al. 1997, Rawson et al. 2002b). More focused application of motivational interviewing and motivational enhancement therapy to stimulant use disorders, developed to improve treatment engagement and achievement of abstinence, is in its infancy (Carroll et al. 2002).

Several other psychosocial treatments might be applied to individuals with ATS use disorders (Marlatt and Gordon 1985). Relapse prevention is also recommended in the TIPS protocol. This approach, easily combined with widely used drug counseling, systematically teaches individuals the skills needed to avoid drug use through training in assertiveness and refusal skills, how to cope with craving, how to deal with relapses, and how to recognize patterns of behavior or thinking that lead to relapse. Again, controlled trials support the efficacy of this approach for individuals with cocaine dependence (Carroll 1994).

Network therapy, meant to engage family and community in supporting drug-free functioning, appears well suited to ATS abuse and dependence, where acquisition appears more linked to community networks than stressful street “buys.”

There is some controversy as to whether these various treatment modalities, applied under real-world conditions, are superior to the widely applied “drug counseling.” Whether or not through certified addiction counselors, which loosely applies group counseling, supportive expression session, and case management (Wells et al. 1994, Woody 2003). The NIDA Cocaine Psychotherapy Study examined the effects of psychotherapy (cognitive behavioral therapy or supportive-expressive psychotherapy), individual drug counseling, or no additional treatment, on cocaine-dependent subjects participating in group-drug counseling. Though all groups displayed reductions in cocaine use and risky sexual behaviors, the combined group-individual drug counseling cohort had superior outcomes to the other three groups, which did not differ significantly from each other (Cris-t Christoph et al. 1999).

Residential treatment for pregnant women and the homeless is likely to be of benefit for stabilization of ATS-dependent subjects, though there is no specific indication for stimulants (Hughes et al. 1995). The prolonged nature of ATS-induced withdrawal, and the association with aggressiveness and violence, will often make inpatient psychiatric stabilization necessary. It is unknown whether transition to therapeutic communities or half-way houses will be of greater benefit to ATS-dependent subjects that those with other substance use disorders, or be superior in outcome to outpatient-based programs (Mueller and Wyman 1997).

Pharmacotherapy for ATS Dependence

As is the case with cocaine use disorders, effective pharmacotherapies for amphetamine use disorders are not available (Sevarino et al. 2000). Pharmacotherapy trials for ATS agonists have not focused on dopaminergic mechanisms, but on serotonergic/noradrenergic mechanisms (Srisurapanont et al. 2001b). Galloway et al. (1996) reported that the tricyclic antidepressant imipramine, improved treatment retention (33.0 median days vs. 10.5 days) in 32 METH-dependent subjects. However, craving, use, and depression scores were not significantly affected. While open-label trials indicated that fluoxetine might be effective in reducing AMPH use in dependent outpatients, Batki et al. (2000), in a randomized, double-blind study failed to confirm this using fluoxetine at 40mg/day in METH-dependent subjects.

It had long been known that depletion of DA and NE with alpha-methyltyrosine would antagonize the acute euphoric affects of AMPH in humans, though tolerance to the effect developed within a week (Jonsson et al. 1971). In a very small study involving four subjects, desipramine, a tricyclic antidepressant with prominent norepinephrine effects, reduced amphetamine use and craving, but did not improve treatment retention (Tennant et al. 1986).

In parallel to the successful use of opiate agonist maintenance therapy for heroin dependence, there are open trials of dexamphetamine elixir, at 10–90/mg per day being used for controlled maintenance of ATS-dependent subjects (Charnaud and Griffiths 1998, White 2000). While randomized, prospective studies are not yet reported, a reduction of intravenous use of one-half to two-thirds was seen in these prior studies.

In conclusion, the main role of pharmacotherapy is acute symptomatic relief, and treatment of comorbid conditions. Behavioral treatments and self-help groups remain the mainstay of treatment for the many individuals suffering from ATS dependence.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

The ICD-10 criteria sets for other stimulant intoxication and withdrawal are almost the same as the DSM-IV-IR criteria sets for amphetamine intoxication and withdrawal except that the ICD-10 diagnostic criteria for research include drug craving as an additional item. ICD-10 combines amphetamines and caffeine into a single substance class, referred to as “other stimulants, including caffeine.”

References

Introduction
Caffeine is the most widely used mood-altering drug (Gilbert 1984). Across the world caffeine use occurs in a variety of different but culturally well-integrated social contexts, such as the coffee break in the United States, teatime in the United Kingdom, and kola nut chewing in Nigeria. In the United States, dietary surveys indicate that 87% of the population consumes food and beverages containing caffeine. Among caffeine consumers, average daily intake is 193 mg, with men aged 35–54 years having the highest intakes (336 mg/day) (Frary et al. 2005). Figure 56–1 shows trends in annual per capita consumption of the three major dietary sources (soft drinks, coffee, and tea).

Table 56–1 shows typical caffeine content in common foods and medications. It is noteworthy that the range of caffeine contents within a class of food or medication can vary widely. Because habitual consumption of coffee or caffeinated soft drinks with meals is so prevalent, it may not be recognized as caffeine consumption. The widespread use of caffeine can make the recognition of psychiatric disorders associated with caffeine use particularly difficult. However, it is important for the psychiatrist to recognize the role of caffeine as a psychoactive substance capable of producing a variety of psychiatric syndromes. In this chapter five disorders associated with caffeine use are reviewed: caffeine intoxication, caffeine withdrawal, caffeine dependence, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder.

Caffeine Intoxication
Diagnosis
Definition and Diagnostic Features
The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) defines caffeine intoxication as a set of symptoms that develop during or shortly after caffeine use (American Psychiatric Association 2000). There may be two kinds of presentation associated with caffeine intoxication. The first presentation is associated with the acute ingestion of a large amount of caffeine and represents an acute drug overdose condition. The second presentation is associated with the chronic consumption of large amounts of caffeine and results in a more complicated presentation.

Caffeine intoxication has long been recognized as a syndrome produced by the ingestion of an excessive amount of caffeine. For example, Rugh (1896) reported the case of a traveling salesman who had nervousness, involuntary contractions in the arms and legs, a sense of impending danger, and sleep disturbance in the context of excessive coffee consumption used to maintain a highly active pace of work. Similar reports of caffeine intoxication can be found throughout the medical literature of the 1800s and early 1900s with observations of motor unrest, insomnia, tachycardia, irritability, headache, emotional lability, anxiety, and gastrointestinal disturbances associated with excessive use of caffeine.
caffeine. Thus, caffeine intoxication represents a psychiatric disorder that has been well described for at least 100 years.

**Assessment**

The primary features of caffeine intoxication can be found in the diagnostic criteria from DSM-IV-TR. The diagnostic decision tree for caffeine intoxication disorder, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder is shown in Figure 56–2. One study that utilized a random-digit-dial telephone survey of 162 users of caffeine, examined the types of symptoms reported by persons who had experienced some features of caffeine intoxication (Hughes et al. 1998). Results from that study showed that two-thirds of participants had experienced at least one of the DSM-IV-TR symptoms related to caffeine intoxication in the previous year. The most common symptoms reported,

**Caffeine Intoxication**

A. Recent consumption of caffeine, usually in excess of 250 mg (e.g., more than 2–3 cups of brewed coffee).

B. Five (or more) of the following signs, developing during, or shortly after, caffeine use:
   1. restlessness
   2. nervousness
   3. excitement
   4. insomnia
   5. flushed face
   6. diuresis
   7. gastrointestinal disturbance
   8. muscle twitching
   9. rambling flow of thought and speech
   10. tachycardia or cardiac arrhythmia
   11. periods of inexhaustibility
   12. psychomotor agitation

C. The symptoms in Criterion B cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder (e.g., an anxiety disorder).

in decreasing order of frequency, were frequent urination, restlessness, insomnia, nervousness, and excitement (all were at rates greater than 20%). In addition, 24% reported heart pounding in response to high caffeine use (although this is not one of the DSM-IV-TR criteria).

In a study of 124 general hospital patients, the most common somatic symptoms patients reported as associated with caffeine intake (i.e., symptoms not specified as associated with either caffeine intoxication or caffeine withdrawal) were in descending order of frequency: diuresis, insomnia,

In addition to the characteristics of caffeine intoxication noted in DSM-IV-TR there have been reports of fever (Reimann 1967), irritability, tremors, sensory disturbances, tachypnea (Greden 1974), headaches (Shirlow and Mathers 1985, Stoffer 1979), vomiting and seizures (Kerrigan and Lindsey, 2005) associated with cases of caffeine intoxication. Although a wide variety of symptoms of caffeine intoxication have been reported, the most common signs and symptoms appear to be anxiety and nervousness, diuresis, insomnia, gastrointestinal disturbances, tremors, tachycardia, and psychomotor agitation.

Epidemiology
Despite the long history of recognition of caffeine intoxication, there is little information available about the prevalence or incidence of caffeine intoxication either in the general community or in selected populations. There is one study that examined caffeine intoxication in the community, and five studies that examined rates of caffeine intoxication in special populations.

The study that addresses the prevalence of caffeine intoxication in the community was briefly mentioned above (Hughes et al. 1998). In that telephone survey of 162 caffeine users in Vermont, two-thirds of the participants reported at least one DSM-IV-TR caffeine intoxication symptom and 7% fulfilled DSM-IV-TR criteria for caffeine intoxication. These results suggest that caffeine intoxication and symptoms related to excessive caffeine use may be quite common in the general community.

Four studies examined the rate of caffeine intoxication in special populations. A recent population-based study of 3,603 adult twins found that 29% reported occasions of feeling ill or shaky or jittery after drinking caffeinated beverages (Kendler et al. 2006). In a 1975 survey of 220 psychiatric patients and control subjects, none of the participants had symptoms of caffeine intoxication (Furlong 1975). A 1976 survey of 135 inpatients on a psychiatric unit found two cases (1.5%) of caffeine intoxication (Winstead 1976). A 1981 survey of college students found 1.3% with high caffeine consumption, and these high caffeine consumers had high levels of symptoms associated with caffeine intoxication (Gilliland and Andress 1981). Finally, a 1990 survey of college students found that 19% reported a history of caffeine intoxication (Bradley and Petree 1990).

Thus, it would appear that the incidence of caffeine intoxication in the general community is about 7% per year, and it may be higher in selected populations at greater risk for caffeine intoxication (e.g., students). However, there clearly is a need for better characterization of both the prevalence and the incidence of caffeine intoxication, using rigorous criteria for the diagnosis and representative sampling techniques.

Comorbidity Patterns
Reports on comorbidity have often failed to distinguish chronic high caffeine consumption from a formal diagnosis of caffeine intoxication. In addition, reports on caffeine intoxication have generally failed to distinguish between a single acute episode of caffeine intoxication and a state of chronic caffeine intoxication.

The previously mentioned study of adult twins found that caffeine toxicity (occasions of feeling ill or shaky or jittery after drinking caffeinated beverages) was significantly and positively associated with each of seven diagnoses: major depression, generalized anxiety disorder, panic disorder,
adult antisocial disorder, alcohol dependence, and cannabis and cocaine abuse/dependence. The odds ratios were similar across all disorders, although it was highest with generalized anxiety disorder (Kendler et al. 2006). There have been case reports of caffeine intoxication occurring in athletes and bodybuilders (Stillner et al. 1978; FitzSimmons and Kidner, 1998) and in patients with eating disorders (Sours 1983, Christo et al. 2003, Pallanti et al. 2006). The symptoms of caffeine intoxication can mimic those of anxiety and mood disorders (Greden 1974).

There are also comorbid conditions associated with excessive caffeine consumption (i.e., habitual use of large amounts of caffeine without evidence of acute caffeine intoxication). Surveys of psychiatric patients have found high rates of excessive caffeine consumption, particularly among patients with schizophrenia (Greden et al. 1978, Rihs et al. 1996, Strassnig et al. 2006, Gurpegui et al. 2006). Furlong (1975) reported that higher coffee consumption was associated with the diagnosis of a personality disorder, and Winstead (1976) reported that higher caffeine consumption was more likely in patients with psychotic disorders, but not in patients with depressive neurotic disorders. Case reports have described patients with chronic schizophrenia eating large amounts of instant coffee powder for the pleasurable effect produced by the coffee (Benson and David 1986).

The relationship between caffeine consumption and anxiety disorders is considered in more detail later (in the section on caffeine-induced anxiety disorder), but it is worth noting here that patients with panic disorder appear to have lower caffeine consumption (Lee et al. 1988), and that patients with panic disorder and patients with generalized anxiety disorder may be more sensitive to the effects of caffeine (Bruce et al. 1992, Boulenger et al. 1984).

Excessive caffeine consumption has repeatedly been observed to be associated with smoking tobacco and alcohol and other substance use disorders (Russ et al. 1988, Christo et al. 2003, cf. section on caffeine dependence).

Another psychiatric condition associated with the excessive consumption of caffeine is delirium, which may be present in cases of extreme caffeine intoxication. For example, caffeine-induced delirium has been reported in a man who acutely consumed coffee, cola, and 800 mg of caffeine (tablets) while competing in the Iditarod dogsled race held between Anchorage and Nome, Alaska (Stillner et al. 1978). He experienced tremor, an alteration in his level of consciousness, anxiety, visual illusions and hallucinations, vertigo, and impaired memory consistent with an episode of delirium. Other cases of probable caffeine-induced delirium have also been reported (McManamy and Schube 1936, Shen and D’Souza 1979).

Although it is extremely rare, another psychiatric condition that can be associated with excessive caffeine consumption is suicide (Tanskanen et al. 2000a, 2000b). After adjusting for potential covariates, one study reported that the risk of suicide was 58% higher among heavy coffee drinkers than moderate coffee drinkers (Tanskanen et al. 2000b).

Finally, heavy caffeine consumption has been shown to be a risk factor for chronic daily headache in adults and in children (Scher et al. 2004, Hering-Hanit and Gadoth 2003).

Course
In the patient who is not tolerant to caffeine, acute caffeine ingestion producing caffeine intoxication is a time-limited condition that will rapidly resolve with cessation of caffeine use, consistent with the relatively short half-life of caffeine (3–6 hours) (Balogh et al. 1992). In a patient who has caffeine intoxication superimposed on chronic caffeine use, abrupt termination of all caffeine use may lead to caffeine withdrawal symptoms (described in detail in the section on caffeine withdrawal). Because symptoms of caffeine withdrawal can partially overlap with symptoms of caffeine intoxication (e.g., nervousness and anxiety), the time course of symptom resolution can be expected to be protracted, lasting several days to a week or more.

Although caffeine intoxication usually resolves without significant complications, adverse events can occur. In 2005, 4,656 caffeine exposures were reported to poison centers in the United States, with half requiring treatment in a health care facility (Lai et al. 2006). Overdose with caffeine may be fatal (Mrvos et al. 1989, Garriott et al. 1985, Kerrigan and Lindsey 2005), and there are reports of suicide death by caffeine overdose (Bryant 1981, Holmgren et al. 2004). If there is evidence that a patient has significantly overdosed on caffeine, then it should be treated as a medical emergency requiring intensive monitoring, symptomatic treatment (e.g., for tachycardia, arrhythmias, and seizures), aspiration of the stomach, and assessment of the serum caffeine level (>100 micrograms/mL is generally considered lethal). Caffeine overdose has also been treated successfully with hemoperfusion or hemodialysis (Nagesh and Murphy 1988, Holstege et al. 2003).

Differential Diagnosis
The diagnosis of caffeine intoxication is based on the history and clinical presentation of the patient. Ideally, the extent of caffeine exposure can also be assessed by a serum or saliva assay of the caffeine level. In the past, caffeine use has often been overlooked in patients presenting with symptoms consistent with a caffeine use disorder (Doucette and Willoughby 1980). However, it may be that there is presently a greater awareness of the deleterious effects of caffeine, making psychiatrists more sensitive to the inclusion of caffeine in a differential diagnosis, and patients more aware of the possible role of excessive caffeine in somatic and psychological symptoms.

Several conditions should be included in the differential diagnosis of caffeine intoxication (Table 56–2). These include other substance abuse-related disorders (amphetamine or cocaine intoxication; withdrawal from sedatives, hypnotics, anxiolytics, or nicotine), other psychiatric disorders (panic disorder, generalized anxiety disorder, mania, sleep disorders), medication-induced side effects (e.g., akathisia), and somatic disorders (e.g., pheochromocytoma, hyperthyroidism, gastroesophageal reflux, arrhythmia). Caffeine intoxication may present with a wide variety of clinical features, and the possibility of caffeine intoxication should be included in the differential diagnosis for patients with nonspecific complaints, or presentations that do not readily fit into a known diagnostic pattern.
Etiology and Pathophysiology

Individual Differences and Genetic Factors
Although caffeine intoxication is clearly related to caffeine ingestion, it is not simply the result of a person's consuming a high dose of caffeine. Rather, caffeine intoxication represents the relationship between the dose of caffeine consumed, the degree of acquired tolerance to caffeine in that person, and the individual's sensitivity to caffeine. In addition to individual differences due to acquired tolerance, substantial differences in sensitivity to caffeine effects have been documented. For instance, drug discrimination studies have shown that the threshold for caffeine discrimination can vary over a tenfold range of doses (Griffiths et al. 1990a, Mumford et al. 1994). Although heavy caffeine consumption is more common in men than women, rates of caffeine toxicity are similar (Kendler et al. 2006).

There is a genetic basis to individual differences to caffeine intoxication. An association has been demonstrated between caffeine-induced anxiety and adenosine A2a receptor gene polymorphisms associated with panic disorder (Alsene et al. 2003, Hamilton et al. 2004). A study of adult twins showed that monozygotic twins had significantly higher concordance rates of caffeine toxicity than dizygotic twins, resulting in an estimated heritability of 45% (Kendler and Prescott 1999). Another twin study demonstrated moderate comorbidity between caffeine toxicity and a wide range of psychiatric and substance use disorders (Kendler et al. 2006). Analysis of these relationships within monozygotic pairs suggest that this relationship is largely correlated rather than causal.

Acquired Tolerance
Tolerance represents a decrease in responsiveness to a drug due to drug exposure. As described in more detail in the section on caffeine dependence, complete tolerance to the subjective effects of caffeine occurs when very high caffeine doses are administered daily (750–1200 mg/day). Thus a sensitive person with no tolerance to caffeine might have signs and symptoms of caffeine intoxication in response to a relatively low dose of caffeine (such as 200 mg, the amount found in a typical serving of brewed coffee) (Table 56–1), whereas another person with a high daily consumption of caffeine would show no evidence of intoxication with a similar dose.

Pharmacological Mechanism of Action
The principal cellular site of action of caffeine is the adenosine receptor, where caffeine functions as an antagonist at both A2A and A1 receptors (Fredholm et al. 1999). Adenosine produces a wide variety of physiological effects, including decreasing spontaneous electrical activity in brain, inhibiting neurotransmitter release in brain, decreasing spontaneous and operant motor activity, dilating central vasculature, producing antidiuresis, inhibiting gastric secretion, and inhibiting gastric secretion and lipolysis (Daly 1993). As an antagonist of adenosine many of caffeine's actions are opposite to those produced by adenosine (e.g., central nervous system stimulation, decreased cerebral blood flow, increased renin release and diuresis, increased gastric secretions, and stimulation of respiration).

Neuropsychological and behavioral studies show that caffeine effects are mediated by blockade at both A2A and A1 receptors (Karcz-Kubicha et al. 2003, Halldner et al. 2004, Kuzmin et al. 2006) and there is evidence that both receptors can form functional receptor heteromers, including A1–A2A, A1–D1, A2A–D2, and A2A–D1 heteromers (Ferre et al. 2005, Fuxe et al. 2005). The relationship between adenosine and dopamine functioning has become an area of particular interest and study. Caffeine enhances dopaminergic activity by competitive antagonism of receptors that are colocalized and functionally interact with dopamine receptors (Ferre et al. 1997, Cauli and Morelli 2005, Fredholm et al. 2005). Basal adenosine functioning exerts a negative modulation of dopaminergic functioning, with activity at A2A and A1 receptors, respectively, affecting D2 and D1 binding characteristics and signaling pathways. Consistent with this mechanism of increased dopaminergic activity, preclinical behavioral studies show that caffeine produces behavioral effects similar to classic dopaminergically mediated stimulants such as cocaine and amphetamine, including increased locomotor activity and stimulant-like discriminative stimulus effects. Also, a number of these effects are blocked by dopamine antagonists (Fredholm et al. 1999, Garrett and Griffiths 1997), or abolished in adenosine receptor knock-out mice (El Yacoubi et al. 2000, Halldner et al. 2004). Furthermore, as discussed in the section on caffeine dependence, caffeine produces dopamine release in the shell of the nucleus accumbens similar to classic drugs of abuse including the stimulants. Although dopaminergically mediated effects may be important to understanding the amphetamine-like stimulant effects of low and moderate doses of caffeine, dopaminergic mechanisms may be only partially relevant to understanding the clinical manifestations of caffeine intoxication that emerge at high toxic doses of caffeine.

Caffeine's direct effects on adenosine and indirect effects on dopamine occur at concentrations similar to those attained after typical dietary doses of caffeine. Caffeine can also exert effects on phosphorylase and intracellular calcium, although with typical dietary doses of caffeine, blood levels of caffeine are believed to be too low to appreciably affect these nonadenosine mechanisms of action. Thus, adenosine antagonism appears to be the primary mechanism for caffeine's effects. It is not known whether these other mechanisms may mediate some of the clinical effects produced when caffeine concentrations are elevated (e.g., as may occur with caffeine intoxication).

Treatment
The first step in evaluating a patient with a possible diagnosis of caffeine intoxication is to obtain a history about all recent caffeine consumption. The possible use of beverages and medications—both prescription and over-the-counter (OTC) diet aids and energy pills—should be reviewed. Some beverages (e.g., caffeine-containing soft drinks) and
medications (e.g., energy pills, aids to combat sleep, or diet pills) may not be recognized by the patient as containing caffeine. The amount of caffeine acutely consumed should help clarify the diagnosis of caffeine intoxication, although it is important to determine whether the patient has been chronically consuming high doses of caffeine. If this is the case, the patient may be tolerant and, therefore, less likely to be experiencing caffeine intoxication. However, some clinicians have reported that caffeine intoxication can occur even in the context of chronic caffeine use. If the patient is unable to provide an accurate history of recent caffeine consumption (e.g., because of delirium after a caffeine overdose), the patient should be emergently evaluated and medically monitored.

The primary approach to the treatment of caffeine intoxication is to teach the patient about the effects of excessive caffeine consumption. In patients who are resistant to accepting the role of caffeine in their presenting symptoms, it may be useful to suggest a trial off of caffeine as both a diagnostic and a potentially therapeutic probe.

**Caffeine Withdrawal**

**Definition and Diagnostic Features**

Symptoms of caffeine withdrawal have been described in the medical literature for more than 170 years (Griffiths and Woodson 1988a). For example, Bridge (1893) reported on a series of patients who had various conditions he thought were associated with the use of coffee or tea. He concluded that the cessation of coffee could be beneficial, although patients were at risk for developing a severe headache acutely with abrupt termination, and he recommended “reducing the rations of coffee gradually through a week or more of time.”

Arguably, the caffeine withdrawal syndrome has been more rigorously and completely characterized than withdrawal from any other drug. A recent review summarized results of 66 reports on caffeine withdrawal, most of which were published within the last 10 years (Juliano and Griffiths 2004). In addition to headache, the best validated caffeine withdrawal symptoms are tiredness/fatigue, sleepiness/drowsiness, dysphoric mood (e.g., miserable, decreased well-being/contentedness), difficulty concentrating, depression, irritability, nausea/vomiting, and muscle aches/stiffness (Table 56–3). Sign and symptom categories that have also been implicated in caffeine cessation include yawning, heavy feelings in arms and legs, work difficulty/unmotivated, craving/strong desire to use caffeine, impaired behavioral and cognitive performance (objectively measured), increased cerebral blood flow, and EEG changes (Juliano and Griffiths 2004).

**DSM-IV-TR Diagnosis of Caffeine Withdrawal**

Although caffeine can produce a withdrawal syndrome, the Substance Use Disorders Work Group for DSM-IV-TR recommended including caffeine withdrawal as a proposed diagnosis rather than an official diagnosis to encourage further research on the range and specificity of caffeine withdrawal symptoms (Hughes 1994). The DSM-IV-TR research criteria for a diagnosis of caffeine withdrawal are shown on this page. In 1994, the Work Group for DSM-IV-TR had several concerns about the inclusion of a diagnosis of caffeine withdrawal in DSM-IV-TR; only headache, fatigue, and drowsiness were well-validated symptoms, the symptoms of fatigue and drowsiness appeared to overlap, and the three caffeine abstinence symptoms had a high prevalence in the general population and also had several other etiologies (Hughes 1994). The great majority of the research literature on caffeine withdrawal has been published since 1994 when the DSM-IV-TR Work Group formulated their criteria for the research diagnosis. This new research literature provides better validation of a wider range of symptoms (Table 56–3). The proposed criteria for a DSM-IV-TR research diagnosis of caffeine withdrawal require the presence of headache and one or more of the following: marked fatigue or drowsiness, marked anxiety or depression, nausea or vomiting. Problems with this approach are that it does not reflect the independence of headache and nonheadache withdrawal symptoms (discussed below), it excludes several well-validated withdrawal symptoms (dysphoric mood, difficulty concentrating, and irritability), and it includes a symptom (anxiety) that was not shown to be valid in double-blind experimental studies. On the basis of the expanded research literature, it has been proposed (Juliano and Griffiths 2004) that part B

of the DSM research criteria be changed to indicate that the caffeine withdrawal diagnosis requires: abrupt cessation of caffeine use or reduction in the amount of caffeine used closely followed by three or more of the following: (1) headache, (2) fatigue or drowsiness, (3) dysphoric mood, depressed mood, or irritability, (4) difficulty concentrating, and (5) nausea, vomiting, or muscle pain/stiffness. The new criteria address the 1994 DSM-IV-TR Work Group concerns that there were too few validated symptoms and there may be overlap between fatigue and drowsiness. Although it remains true that some of the proposed symptoms have high prevalence and may have other etiologies, this is also true of other withdrawal diagnoses recognized by DSM (e.g., cocaine withdrawal, nicotine withdrawal and opioid withdrawal).

**Headache**

The most common feature of caffeine withdrawal is headache (Table 56–4) (Lader et al. 1996, Juliano and Griffiths 2004). About 50% of individuals in double-blind studies report headache, which is often moderate to severe in intensity. Caffeine withdrawal headache is typically described as gradual in development, diffuse, throbbing, and sometimes accompanied by nausea and vomiting. It is relieved with caffeine consumption and it may be worsened with physical exercise and Valsalva maneuver. Double-blind studies of caffeine withdrawal have shown that headache generally occurs 12–24 hours after the last dose of caffeine (mean 19 hours), although headache onset as late as about 40 hours has been documented. Caffeine withdrawal headache usually resolves within 2–4 days, although some subjects continue to report sporadic headaches for as long as 11 days after cessation of caffeine use (Juliano and Griffiths 2004).

Clinical reports, correlation analyses, and cluster analysis of withdrawal symptoms indicate that nonheadache signs and symptoms of caffeine withdrawal do not always covary with the presence of headache, and can occur in the absence of headache (Juliano and Griffiths 2004). This indicates that nonheadache symptoms represent distinct features of the caffeine withdrawal syndrome that can occur independently of headache.

**Clinically Significant Distress or Impairment in Daily Functioning in Caffeine Withdrawal**

When symptoms of caffeine withdrawal occur, the severity can vary from mild to extreme. At its worst, caffeine withdrawal has been repeatedly documented to produce clinically significant distress or impairment in daily functioning and, on rare occasions, to be totally incapacitating (Bridge 1893, 1990b, Lader et al. 1996, Strain et al. 1994, Dreisbach and Pfeiffer 1943, Kingdon 1833, Silverman et al. 1992, Greden et al. 1980, Goldstein et al. 1969, Rainey 1985, Cacciatore et al. 1996, Hampl et al. 1994, Richards et al. 2004, Svikis et al. 2005). For example, in a double-blind caffeine withdrawal evaluation, 73% of individuals whose pattern of caffeine use met criteria for DSM-IV-TR substance dependence on caffeine reported functional impairment in normal activities during an experimental withdrawal phase (Strain et al. 1994).

Several rigorous blind studies indicate that the incidence of moderate to severe headache is about 50% in healthy normal subjects abstaining from caffeine (Lader et al. 1996, Dreisbach and Pfeiffer 1943, Silverman et al. 1992). One of these studies reported that 28% of those reporting headache also reported nausea and sickness (Lader et al. 1996). Dews et al. (1999) reported that 22% of 18 subjects who previously reported experiencing withdrawal symptoms showed substantial decreases in their ratings of daily functioning (e.g., work and leisure activities) during caffeine abstinence. The relatively lower rate of severe withdrawal symptoms in this study may be due to methodological shortcomings (Griffiths et al. 2003). On the basis of a comprehensive review of the literature, the overall median incidence of clinically significant distress or functional impairment was estimated to be 13% in prospective experimental studies and 9% in retrospective surveys in normal subjects (Juliano and Griffiths 2004).

**Assessment**

The key steps in establishing a diagnosis of caffeine withdrawal are to determine the history of the person’s caffeine consumption from all dietary sources, and then establish whether there has been a significant decrease in caffeine intake. The diagnostic decision tree for caffeine dependence disorder and caffeine withdrawal disorder is shown in Figure 56–3. Caffeine withdrawal is probably more common than is generally recognized, and it seems there is a tendency for people to attribute the symptoms of caffeine withdrawal to other etiologies besides caffeine (e.g., having the flu, or a bad day). Caffeine withdrawal may be particularly common in medical settings where patients are required to abstain from food and fluids, such as before surgical procedures and certain diagnostic tests. In addition, caffeine withdrawal may occur in settings where the use of caffeine-containing products is restricted or banned, such as inpatient psychiatric wards.

**Caffeine Withdrawal in Children and Newborn Infants**

Although most research on caffeine withdrawal has been conducted in adults, several studies document that children also experience withdrawal effects during caffeine abstinence (Goldstein and Wallace 1997, Bernstein et al. 1998, 2002, Hale et al. 1995). There is also one report of eight infants with suspected caffeine withdrawal born to mothers who had heavy caffeine consumption during their pregnancies (range: 200–1800 mg/day) (McGowan et al. 1988). Symptoms began an average of 19 hours after birth, were primarily irritability, jitteriness and vomiting, and resolved spontaneously.

**Epidemiology**

There are two types of studies that have examined the prevalence/incidence of caffeine withdrawal. In the first, caffeine withdrawal is experimentally induced, and in the second, there is an epidemiologic assessment of the prevalence/incidence of caffeine withdrawal, usually through the use of some form of a retrospective questionnaire. The
The median percentage of individuals reporting headache in 19 experimental studies was 47%, ranging from 9% to 100% across studies. In 7 studies that assessed headache severity, the median percentage of individuals reporting moderate, severe or maximum headache was 50% (Juliano and Griffiths 2004). On the basis of a comprehensive review of the literature, the median incidence of clinically significant distress or functional impairment from caffeine withdrawal in prospective experimental studies with normal subjects was 13%, ranging from 10 to 55%. This rate is similar to the 14% rate of functional impairment reported in a recent caffeine withdrawal trial in pregnant women (Svikis et al. 2005), but lower than the 73% rate of functional impairment observed in individuals who met criteria for DSM-IV-TR substance dependence on caffeine (Strain et al. 1994).

Survey studies have also been conducted to determine the prevalence/incidence of caffeine withdrawal. Two population-based survey studies showed a 24% incidence of caffeine withdrawal using the DSM-IV-TR research criteria (Hughes et al. 1998, Kendler and Prescott 1999). In the study by Hughes and colleagues, 44% of caffeine users reported having stopped or reduced caffeine use for at least 24 hours in the past year. Of those, 41% reported that they experienced one or more DSM-IV-TR-defined caffeine withdrawal symptom. Among individuals who stopped caffeine use in an attempt to abstain permanently, 71% reported experiencing one or more DSM-IV-TR-defined caffeine withdrawal symptom. Among individuals who stopped caffeine use in an attempt to abstain permanently, 71% reported experiencing one or more DSM-IV-TR-defined symptoms, and 24% reported having headache plus other symptoms that interfered with performance. In a review of 7 survey studies, the median percentage of caffeine users reporting caffeine withdrawal headache was also 24%, ranging between 8 and 56% (Juliano and Griffiths 2004). Finally, in a more recent survey study of women who abstained from caffeine for a day or more, 49%, 39%, and 2% reported headache, fatigue, and nausea or vomiting, respectively (Svikis et al. 2005). On the basis of a comprehensive review of the literature, the incidence of clinically significant distress or functional impairment from caffeine withdrawal varied between 2.6 and 11% (median 9%) in general survey studies, and was 21% in caffeine-dependent adolescents (Juliano and Griffiths 2004, Oberstar et al. 2002).

It is possible that survey studies underestimate the rate of caffeine withdrawal. Many caffeine consumers may be unaware of their vulnerability to caffeine withdrawal symptoms, because their routine habitual consumption never involves a period of sustained abstinence, and they may misattribute withdrawal symptoms such as headache, nausea, and muscle aches to other ailments such as viral infection. Furthermore, since as little as 25 mg/day of caffeine is sufficient to suppress withdrawal (Evans and Griffiths 1999), even small amounts of caffeine that are unknowingly consumed during presumed caffeine abstinence may result in underestimates of the frequency of withdrawal.

Comorbidity Patterns

Patients with high daily caffeine consumption (Evans and Griffiths 1999, Weber et al. 1997), or patients with a history of frequent headaches (Weber et al. 1997) may be at increased risk for developing caffeine withdrawal or caffeine withdrawal headaches. A study of adult twins found that a measure reflecting caffeine withdrawal (comprised of summing several caffeine withdrawal symptoms plus tolerance) was significantly and positively associated with each of seven diagnoses: major depression, generalized anxiety disorder, panic disorder, adult antisocial disorder, alcohol dependence, and cannabis and cocaine abuse/dependence (Kendler et al. 2006).

**Postanesthesia Headache and Caffeine Withdrawal**

Headache is one of the most frequent postoperative side effects after general anesthesia, with the incidence varying from 13 to 80% (Fennelly et al. 1991) and caffeine abstinence being a contributor. Studies in patients required to abstain from caffeine in preparation for an operative procedure have shown that a history of preoperative caffeine is associated with an increased risk for postoperative headache.

Chapter 56 • Substance Abuse: Caffeine Use Disorders

1027

Nikolajsen et al. 1994, Fennelly et al. 1991, Galletly et al. 1989), although this risk may be dose-related (Fennelly et al. 1991, Galletly et al. 1989). In patients with a history of caffeine consumption who received caffeine on the day of a surgical procedure, the rate of postoperative headaches was lower than in those who received placebo (Weber et al. 1997, Hampl et al. 1995).

Course

Caffeine withdrawal generally begins 12–24 hours after discontinuing caffeine use. The peak of caffeine withdrawal generally occurs within 20–50 hours, and the duration of caffeine withdrawal is generally 2 days to about 1 week (Juliano and Griffiths 2004). The possibility of withdrawal headaches occurring up to 21 days has been suggested (Richardson et al. 1995). An example of the time course of caffeine withdrawal symptoms is shown in Figure 56–4. In this study four volunteers, who initially received 100 mg/day of caffeine in capsules, were switched under double-blind conditions to placebo for a period of 12 days (Griffiths et al. 1990b). Symptoms of headache, lethargy/fatigue/tired/sluggish, and impaired concentration peaked on days 1 or 2 after placebo substitution and progressively returned toward prewithdrawal levels over about a week (Figure 56–4).

Differential Diagnosis

Caffeine withdrawal should be considered when evaluating individuals presenting with headaches, fatigue, sleepiness, mood disturbances or impaired concentration. The differential diagnosis of caffeine withdrawal includes: viral illnesses; sinus conditions; other types of headaches such as migraine, tension, postanesthetic; other drug withdrawal states such as amphetamine or cocaine withdrawal; and idiopathic drug reactions.

Etiology and Pathophysiology

Individual Differences and Genetic Factors

There is considerable variability, both between people and within the same person across episodes, in the manifestations, time course, and severity of caffeine withdrawal (Griffiths et al. 1990b, Hughes et al. 1993). Other than the role of chronic maintenance dose (discussed below), very little is known about the determinants of individual differences in caffeine withdrawal. The results of one study suggested that individuals who eliminated caffeine slowly were less likely to experience sedation during withdrawal (Lader et al. 1996). Two studies suggest that females may be more likely than males to report functional impairment produced by caffeine withdrawal (Strain et al. 1994, Dews et al. 1999).

There is evidence that genetic factors may play a role in some differences between individuals. One study of female twins found that there was a significantly greater concordance of DSM-IV-TR-defined caffeine withdrawal among monozygotic than dizygotic twins, resulting in an estimated heritability of 35% (Kendler and Prescott 1999).

Pharmacological Factors

Maintenance Dose of Caffeine

Several studies have found either the presence of caffeine withdrawal, or its severity are more likely as the daily maintenance dose of caffeine is increased (Evans and Griffiths 1999, Nikolajsen et al. 1994, Fennelly et al. 1991, Galletly et al. 1989), although this relationship is relatively weak because it has not been observed in some studies (Hughes...
et al. 1993, Lader et al. 1996), and some studies have shown no or only very mild symptoms after stopping high doses of caffeine in some individuals (Griffiths et al. 1986, Strain et al. 1994). It has been shown that caffeine withdrawal can occur with surprisingly low doses of caffeine—as low as 100 mg/day (Griffiths et al. 1990b, Evans and Griffiths 1999), which is the equivalent of about one cup of brewed coffee or two to three caffeinated soft drinks per day (Table 56–1).

**Duration of Caffeine Exposure**

Caffeine withdrawal has been shown to occur after relatively short-term exposure to daily caffeine (Evans and Griffiths 1999, Dreisbach and Pfeiffer 1943). One study showed that significant withdrawal occurred after only 3 consecutive days of 300 mg/day caffeine, with somewhat greater severity shown after 7 and 14 consecutive days of exposure (Evans and Griffiths 1999). Another study showed that caffeine withdrawal headache occurred in three individuals who normally abstained from caffeinated beverages but were given 600–750 mg/day caffeine for 6 or 7 days (Dreisbach and Pfeiffer 1943).

**Caffeine Suppression of Caffeine Withdrawal**

Low doses of caffeine are capable of suppressing caffeine withdrawal (Watson et al. 2000). One study showed that a small dose of only 25 mg/day was sufficient to suppress caffeine withdrawal headache in people maintained on 300 mg/day (Evans and Griffiths 1999). This finding suggests that a substantial percentage reduction in caffeine consumption is necessary to manifest the full caffeine withdrawal syndrome.

**Pharmacological Mechanism of Action**

Antagonism of adenosine at adenosine receptors is the primary molecular mechanism underlying most of the central and peripheral physiological effects of caffeine after acute administration (see section on “caffeine intoxication”). Chronic caffeine consumption has been shown to produce compensatory upregulation of the adenosine system, resulting in an increase in functional sensitivity to adenosine during caffeine withdrawal (Paul et al. 1993, Kaplan et al. 1993, Varani et al. 1999). Because adenosine produces sedation and cerebral vasodilation (Daly 1993) and has been implicated in headache (Guieu et al. 1998), increased sensitivity to endogenous adenosine, particularly in vascular and neural tissue in brain, may be a mechanism underlying the common caffeine withdrawal symptoms of fatigue and headache. Studies have shown that caffeine abstinence produces increases in cerebral blood flow and cerebral blood flow velocities (Field et al. 2003, Jones et al. 2000, Courtierre et al. 1997, Mathew and Wilson 1985). These findings are consistent with a vascular explanation of caffeine withdrawal symptoms since blood flow has been implicated in headache (Moskowitz et al. 1989, Olesen 1991). Another physiological effect documented during caffeine abstinence is a change in quantitative EEG. Two studies (Jones et al. 2000, Reeves et al. 1995) showed increases in theta activity, an effect generally correlated with drowsiness, which is a common caffeine withdrawal symptom.

**Treatment**

There have been few studies attempting to address the treatment of caffeine withdrawal, although it has frequently been observed that the symptoms of caffeine withdrawal can be alleviated with the consumption of caffeine (Evans and Griffiths 1999, Dreisbach and Pfeiffer 1943), and this approach is probably best. One report indicated that experimentally induced caffeine withdrawal headaches responded to aspirin (Dreisbach and Pfeiffer 1943). If the medical recommendation is made to eliminate or substantially reduce caffeine consumption, then it may be useful to recommend a tapering dose schedule rather than abrupt discontinuation. Caffeine tapering (or “fading”) is described in more detail in the section on “caffeine dependence.”

---

**Clinical Vignette 1: Caffeine Withdrawal**

Ms. E, a 37-year-old married woman, presented with a chief complaint of episodic headaches, especially noted on weekends. Her family history was notable for alcoholism in her mother, but there was no other psychiatric illness in the family. She was a college graduate employed full time as a clerk, had been married for 16 years, and had two healthy children. She met her husband in college and described her marriage as stable and her husband as supportive. She did not smoke tobacco, drank alcohol rarely (once every 2 to 3 months, typically one to two drinks), and did not use illicit drugs. Ms. E was not taking prescription medications, had no chronic medical illnesses, and had no past psychiatric history.

She reported that she began consuming caffeine by drinking soft drinks as a child and regularly drank soft drinks as she was growing up. She began drinking coffee in college and used coffee regularly when she needed to study late at night. Her current beverage of choice was coffee, which she drank without cream or sweetener, and she drank a total of five to six large mugs each day. There was a coffee maker in her office, and her first consumption of coffee every morning was at work. She spaced her subsequent coffee use during the course of the day, with her last mug late in the afternoon at work. At one point when she was scheduled for outpatient surgery, staff had considered canceling the procedure because of her developing a severe headache after morning abstinence from caffeine. When pregnant, she had tried but had been unable to reduce her use of coffee.

She reported that she typically developed headaches in the late mornings or early afternoons and described them as diffuse, throbbing headaches that were bilateral. She had no aura, no photophobia, and no nausea or vomiting. The headaches were not clearly related to stress, and she thought they occurred primarily on weekends. Other symptoms associated with her headaches included feeling “dragged out,” tired, and sleepy. She had tried taking aspirin and acetaminophen for the headaches and reported only partial relief with these medications. A work-up by her primary care physician revealed no disease that would account for her headaches.

Ms. E’s history of caffeine use and the nature of her headaches suggested that she might be experiencing caffeine withdrawal. On weekends, she would not drink coffee. She was counseled to try drinking a mug of coffee the next time she felt her characteristic headache, and she found this intervention produced full relief from her headache and also alleviated her feeling of lethargy. She then underwent a program of caffeine fading to decrease the overall amount of caffeine she was consuming. Once she achieved a steady level of one mug of coffee per day, she found she was able to skip a day of consuming coffee without experiencing a headache.
Caffeine Dependence

Diagnosis

Definition and Diagnostic Features

Before discussing the definition of caffeine dependence using DSM-IV-TR criteria, it is useful to distinguish physical dependence from a clinical diagnosis of substance dependence. Physical dependence is indicated by the presence of a withdrawal syndrome after cessation of use of the substance. A clinical diagnosis of dependence encompasses several features of pathologic use of a psychoactive substance, which can include (but is not limited to) evidence of physical dependence. These distinctions between physical dependence and a clinical syndrome of dependence often have clouded discussions of caffeine dependence. As described in the previous section, numerous reports now document the existence of a caffeine withdrawal syndrome indicating that caffeine can produce physical dependence. Although considerably fewer studies have been published, there is growing evidence that caffeine can also produce a syndrome of clinical dependence. Currently, DSM-IV-TR utilizes a set of generic criteria to define a clinical syndrome of dependence. Notably, DSM-IV-TR states, “A diagnosis of Substance Dependence can be applied to every class of substances except caffeine.” It is noteworthy, however, that a diagnosis of substance dependence due to caffeine is recognized by ICD-10 (WHO 1992a, 1992b), the international diagnostic system developed by the World Health Organization that uses very similar diagnostic criteria to DSM-IV-TR.

The clinical features of individuals with caffeine dependence were described in a series of 16 cases described by Strain et al. (1994). Most of these individuals reported physical or psychological problems from caffeine use which had prompted multiple unsuccessful attempts to cut down or quit caffeine use, often in response to physicians’ recommendations. Most reported tolerance to caffeine and withdrawal when attempting to completely abstain. A double-blind withdrawal trial showed functional impairment in most cases. For the group, median daily caffeine intake was 357 mg with a wide range of 129–2,548 mg. The preferred vehicle was almost equally divided between soft drinks and coffee.

Clinically Significant Distress or Impairment Associated with Caffeine Dependence

Much in the same way that cigarette smoking was not considered a “real” form of drug dependence several decades ago, personal experience with normative caffeine use may render some clinicians relatively insensitive to the extent of distress or impairment associated with caffeine dependence in some individuals. A brief description of the three diagnostic criteria most relevant to understanding the clinical significance of the syndrome is presented below.

Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
   a. a need for markedly increased amounts of the substance to achieve intoxication or desired effect
   b. markedly diminished effect with continued use of the same amount of the substance

2. Withdrawal, as manifested by either of the following:
   a. the characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the criteria sets for withdrawal from the specific substances)
   b. the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms

3. The substance is often taken in larger amounts or over a longer period than was intended

4. There is a persistent desire or unsuccessful efforts to cut down or control substance use

5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects

6. Important social, occupational, or recreational activities are given up or reduced because of substance use

7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Substance Use is Continued Despite Knowledge of having a Persistent or Recurrent Physical or Psychological Problem That is Likely to have been Caused or Exacerbated by the Substance

Fourteen percent of caffeine users in a general population survey met this criterion, with most (13%) reporting that a physician or counselor had advised them to stop or reduce caffeine use within the last year (Hughes et al. 1998). Medical and psychological problems attributed to caffeine included heart, stomach and urinary problems, and complaints of anxiety, depression, insomnia, irritability, and difficulty thinking. A higher rate of endorsement of this criteria (43%) occurred in a study of pregnant women who had been advised to quit caffeine use during pregnancy (Svikis et al. 2005). When asked about caffeine use prior to pregnancy, 21% indicated that they had previously been told by a health care professional that they should cut back or quit caffeine because of a medical condition including, fibrocystic breast disease, headaches, pregnancy, insomnia, and stomach problems. Not surprisingly, the highest rates of endorsement of this criterion of
continued use despite harm has come from studies that interviewed caffeine-dependent individuals. In four such studies, the prevalence varied from 57 to 94% (Strain et al. 1994, Oberstar et al. 2002, Richards et al. 2004, Jones and Lejuez 2005). In the case series described by Strain et al. 44% of the subjects reported physical conditions such as acne rosacea, pregnancy, palpitations, and gastrointestinal problems that had led physicians to recommend reduction or elimination of caffeine; all had failed to comply with the recommendation.

**Persistent desire or unsuccessful efforts to cut down or control substance use**

The desire to control caffeine use is usually closely related to the recognition of an associated physical or psychological problem, often identified by a physician as described above. In two survey studies, the rate of endorsement of this criterion was 56% (Hughes et al. 1998) and 45% (Svikis et al. 2005). In four studies of caffeine-dependent individuals, the prevalence varied from 60 to 89% (Strain et al. 1994, Oberstar et al. 2002, Richards et al. 2004, Jones and Lejuez 2005). In the study by Richards et al. 82% of a group of 38 individuals were sufficiently distressed by their caffeine use to enroll in a caffeine treatment study.

**Withdrawal**

Many caffeine-dependent individuals continue to use caffeine to avoid experiencing withdrawal symptoms. In four studies of caffeine-dependent persons, the rate of endorsement of withdrawal or use to avoid withdrawal ranged from 73 to 100% (Strain et al. 1994, Oberstar et al. 2002, Richards et al. 2004, Jones and Lejuez 2005). As described in more detail in the prior section on the caffeine withdrawal diagnosis, symptoms of caffeine withdrawal can vary from none to extreme. On the basis of a comprehensive review of the literature, the overall median incidence of clinically significant distress or functional impairment was estimated to be 13% in prospective experimental studies in normal subjects and 9% in retrospective surveys in normal subjects (Juliano and Griffiths 2004).

**Assessment**

Caffeine dependence may be an unrecognized condition with a higher prevalence than is generally appreciated. Clinicians do not typically think to inquire about caffeine use and about problematic use consistent with a diagnosis of caffeine dependence (see Figure 56–3 for diagnostic decision tree). However, probing for evidence of caffeine dependence may be useful, and it would be reasonable to focus upon the DSM-IV-TR criteria for dependence that are more appropriate for a substance that is widely available and generally culturally accepted. Thus, the clinician should probe for evidence of tolerance, withdrawal, continued use despite a doctor’s recommendation that the person cut down or stop using caffeine, use despite other problems associated with caffeine, often using larger amounts or over a longer period than intended, or persistent desires and/or difficulties in decreasing or discontinuing use. For research purposes, a section for the diagnosis of caffeine dependence according to DSM-IV-TR or *International Classification of Diseases, 10th Revision* (ICD-10) criteria is now available on the Composite International Diagnostic Interview-Substance Abuse Module (CIDI-SAM), which is a reliable and valid structured interview focused on substance use disorders (Cottler et al. 1989, Compton et al. 1996).

**Epidemiology**

Two survey studies provide information on the prevalence of caffeine dependence in the general population based upon standardized diagnostic criteria. In a random telephone survey of residents of Vermont (Hughes et al. 1998), 162 out of the 202 surveyed participants reported current caffeine use. Assessing the seven generic DSM-IV-TR criteria for dependence, 30% of the 162 current caffeine users fulfilled criteria for a diagnosis of caffeine dependence by endorsing three or more dependence criteria. When just the four criteria that seemed most applicable to caffeine were assessed: (use despite harm; desire to quit; withdrawal; and tolerance), only 9% fulfilled three or more criteria. Using all seven criteria, Svikis et al. 2005 reported a 57% lifetime prevalence of caffeine dependence among 44 women who reported some caffeine use in the three months before becoming pregnant.

Further information about rates of endorsement of the individual criteria for caffeine dependence is provided by five published reports of individuals who fulfilled criteria for dependence (Strain et al. 1994, Oberstar et al. 2002, Richards et al. 2004, Jones and Lejuez 2005). Rates of endorsement, respectively, of the four most relevant criteria were (1) use despite harm (94%, 58%, 84%, 57%); (2) desire to quit (81%, 83%, 89%, 60%); (3) withdrawal (94%, 100%, 97%, 73%); and (4) tolerance (75%, 92%, 76%, 70%).

**Comorbidity Patterns**

Comorbid conditions associated with excessive caffeine consumption are discussed in the previous section on caffeine intoxication. Four studies provide information about comorbidity in individuals with caffeine dependence. In a previously described study of 44 pregnant caffeine-using women (Svikis et al. 2005), those who had a caffeine dependence diagnosis were almost nine times more likely to report a history of daily cigarette smoking, compared to women without the diagnosis (44% vs. 5%). Furthermore, women with both caffeine dependence and a family history of alcoholism were six times more likely to have a lifetime diagnosis of alcohol abuse or dependence. In the study described above by Strain et al. (1994), which characterized DSM-IV-TR-diagnosed caffeine dependence in 16 adults, it was found that two subjects (13%) had an additional current psychiatric diagnosis (both being anxiety disorders), and 69% had other psychiatric disorders in remission. Most commonly, these other disorders were other psychoactive substance use disorders (63%) followed by mood disorders (44%), anxiety disorders (25%), or eating disorders (19%). Among the psychoactive substance use disorders, the most commonly abused substance was alcohol; 57% of the participants in the study had a past diagnosis of alcohol abuse or dependence. Five of the subjects in the study (32%) were nicotine cigarette smokers and, notably, four of these five had a history of an alcohol disorder (suggesting a clustering of caffeine dependence, smoking and alcohol abuse/dependence, as discussed below). A third study showed that the severity of caffeine dependence was significantly correlated with the severity of the alcohol dependence, however, dependence on caffeine and nicotine were not correlated (Hughes et al. 2000). A final study, which compared 5 caffeine-dependent adolescents with 16 noncaffeine-dependent...
adolescents, found no significant differences between the
groups in rates of various psychiatric disorders including
nicotine and alcohol dependence (Oberstar et al. 2002).

Course
While there are no studies that have specifically examined the
course and natural history of caffeine dependence, like other
drug dependence syndromes caffeine dependence appears
to be a chronic relapsing disorder. In the study described
above by Strain et al. (1994), caffeine dependent partic-
pants reported recurrent efforts to discontinue caffeine use,
with failures to discontinue use or frequent relapses.

Differential Diagnosis
The diagnosis of caffeine dependence includes symptoms
that can also contribute to a diagnosis of caffeine intoxication
and caffeine withdrawal, and both of these conditions
should be included in the differential diagnosis of a patient with pos-
sible caffeine dependence. Since intoxication and withdrawal
symptoms can contribute to the diagnosis of dependence,
conditions that overlap with these caffeine-related disorders
should also be considered (and are reviewed above in their
respective sections). When considering a patient for a possible
diagnosis of caffeine dependence, the clinician should also
consider other substance dependence syndromes—especially
those related to stimulants—in the differential diagnosis.
Finally, the possible presence of other psychiatric condi-
tions, such as depressive and anxiety disorders, should be
assessed. These disorders may be more commonly found
among patients with caffeine dependence, and some of their
presenting features (e.g., low mood, anxiety, disturbed sleep)
can overlap with the symptoms of caffeine intoxication and
withdrawal which commonly occur in caffeine dependence.

Etiology and Pathophysiology

Genetic Factors
Genetic studies suggest that caffeine use problems have an
underlying biological basis, part of which may be shared with
other commonly abused substances. One study examined
women who were instructed to stop caffeine use during their
pregnancy (Svikis et al. 2005). Women with a lifetime diagno-
sis of caffeine dependence and a family history of alcoholism
had higher levels of caffeine use and lower rates of abstinence
throughout pregnancy, and also reported higher rates of past
cigarette smoking and problematic use of alcohol and other
drugs. Twin studies comparing monozygotic and dizygotic
twins showed heritabilities of heavy caffeine use, caffeine tol-
ance, and caffeine withdrawal that ranged between 35 and
77% (Kendler and Prescott 1999, Swan et al. 1997, Pedersen
1981, Partanen et al. 1966). Other twin studies examining caf-
feine use, alcohol use, and cigarette smoking concluded that
a common genetic factor (polysubstance use) underlies the
use of these three substances, with 28–41% of the heritable
effects of caffeine use (or heavy use) shared with alcohol and
smoking (Swan et al. 1997, Hettema et al. 1999).

Behavioral/Psychological Factors

Caffeine Subjective Effects
Many studies have shown that caffeine in low to moderate
doses (20–200 mg) produces mild positive subjective effects
of increased feelings of well-being, alertness, energy, con-
centration, self-confidence, motivation for work, and desire
to talk to people (Griffiths et al. 2003). The profile of posi-
tive effects with caffeine is qualitatively similar to that pro-
duced by d-amphetamine and cocaine, which may reflect a
common dopaminergic mechanism of action. High doses
of caffeine (e.g., 800 mg) produce negative subjective effects
such as anxiety and nervousness, especially in people who
are not tolerant to caffeine (Chait 1992, Evans and Griffiths

Caffeine Reinforcement
Consistent with its ability to produce mild positive subjective
effects, low to moderate doses of caffeine have also been
shown to function as a reinforcer in humans—that is,
when given the choice under experimental conditions, some
people will consistently choose to consume caffeine rather
than placebo (Griffiths et al. 2003). The profile of positive
subjective and reinforcing effects may help explain the wide
and regular consumption of caffeine containing substances.
However, not everyone uses caffeine, and it appears that
some people tend to prefer caffeine and others do not. Caffe-
ine choosers tend to report positive subjective effects from
caffeine, while nonchoosers report negative subjective effects
(Goldstein et al. 1969, Evans and Griffiths 1992), and people
who have symptoms of caffeine withdrawal when they
abstain from caffeine are more likely to choose to consume
caffeine when given the choice (Hughes et al. 1993).

Caffeine Conditioned Flavor Preferences
Studies have shown that repeated pairing of a novel fla-
avored drink with caffeine results in increased ratings of
flavor preference, while pairing of a novel flavored drink
with placebo results in decreased ratings of pleasantness
In caffeine dependence, it seems likely that the development
of such conditioned flavor preferences over many days of
self-administration plays a role in development of strong
preferences for specific types or even brands of caffeine-
containing beverages.

Caffeine Tolerance
Tolerance refers to a decrease in responsiveness to a drug
due to drug exposure. Complete tolerance to caffeine’s sub-
jective, pressor, and neuroendocrine effects has been demon-
strated when very high doses of caffeine (750–1200 mg/day
spread throughout the day) are administered daily (Evans
to the sleep disruptive effects of caffeine has also been dem-
onstrated (Bonnet and Arand 1992). At lower doses similar
to those usually consumed, complete caffeine tolerance does
not occur. Two survey studies indicate 8% (Hughes et al.
1998) and 50% (Svikis et al. 2005) of current caffeine users
reported tolerance (Hughes et al. 1998), whereas the preva-
ience of tolerance ranged from 70 to 92% in four studies of
caffeine dependent individuals (Strain et al. 1994, Oberstar
Although tolerance is one of the criteria for making a diag-
nosis of caffeine dependence (see DSM-IV-TR criteria for
substance dependence), it is not clear what role the develop-
ment of tolerance may have in the development of clinical
dependence upon caffeine.
Role of Caffeine Withdrawal in Maintaining Caffeine Consumption

Caffeine withdrawal, described in detail in a separate section above, is a distinct clinical syndrome characterized by symptoms including headache, fatigue, sleepiness, dysphoric mood, difficulty concentrating, depression, irritability, nausea/vomiting, and muscle aches/stiffness (Table 56–3). Caffeine consumption alleviates caffeine withdrawal symptoms and avoidance of withdrawal symptoms associated with caffeine abstinence has been shown to be an important mechanism of the reinforcing effects of caffeine (Juliano and Griffiths 2004). Withdrawal also plays an important role in the development of preferences for flavors paired with caffeine (Rogers et al. 1995, Yeomans et al. 1998, Tinley et al. 2003).

Caffeine Use and Alcohol or Drug Abuse

The conclusion suggested by the genetic studies described above is that a common genetic factor underlies joint use of caffeine, cigarettes, alcohol, and other drugs. This is consistent with findings of studies on the co-occurrence of use of caffeine, nicotine and alcohol (Kozlowski et al. 1993, Talcott et al. 1998). Kozlowski et al. (1993) found that severity of alcoholism was directly related to use of caffeine and cigarettes, and they conclude that dependence on caffeine, nicotine and alcohol may be governed by the same factors. Other studies indicate that heavy use of caffeine is related to heavy use of alcohol (Istvan and Matarazzo 1984) and that the severity of caffeine dependence increases as the severity of alcohol dependence increases (Hughes et al. 2000). Significantly higher levels of caffeine consumption have also been noted in abstinent alcoholic individuals versus nonalcoholic individuals (Doucette and Willoughby 1980). Other groups at risk may include substance abusers (Russ et al. 1988, Hays et al. 1998, Christo et al. 2003). A study of individuals whose pattern of caffeine use fulfilled DSM-IV-TR diagnostic criteria for substance dependence on caffeine found that almost 60% had a past diagnosis of alcohol abuse or dependence (Strain et al. 1994).

Caffeine Use and Nicotine/Cigarette Smoking

Epidemiological studies have shown that cigarette smokers consume more caffeine than nonsmokers (Istvan and Matarazzo 1984, Swanson et al. 1994), and experimental studies have shown that cigarette smoking and coffee drinking tend to covary temporally within individuals (Emurian et al. 1982, Lane 1996). Higher consumption of caffeine in smokers may be partly due to the increased metabolism of caffeine in smokers (Brown et al. 1988, Parsons and Neims 1978). As described above, twin studies and a study by Kozlowski et al. (1993) also indicate the co-occurrence of caffeine use and cigarette smoking, and Svikis et al. (2005) reported that women fulfilling caffeine dependence diagnostic criteria were more likely to report a history of daily cigarette smoking than women without the diagnosis. However, one study showed no correlation between severity of caffeine and nicotine dependence when the number of diagnostic criteria endorsed were used as the measure of severity (Hughes et al. 2000). Preclinical research indicates that chronic caffeine administration can enhance the reinforcing effects of nicotine (Tanda and Goldberg 2000).

Energy Drinks and Caffeine as a “Gateway” Drug

A notable marketing trend in the United States has been the recent emergence of a new class of high caffeine energy drinks with suggestive names such as “Full Throttle,” “AMP Energy” and “Cocaine.” Advertising, which is targeted primarily to young males, directly promote stimulant and performance enhancing effects of these products and appear to glorify drug use. As discussed above, an association between heavy caffeine use, smoking, and alcohol/drug abuse has been shown. Whether caffeine serves as a “gateway” to other forms of drug dependence as suggested by some studies (Collins et al. 1997, Pallanti et al. 2006) bears further investigation.

Pharmacological Mechanism of Action

As has been discussed in the sections on caffeine intoxication and caffeine withdrawal, antagonism of the endogenous neuromodulator adenosine at adenosine receptors is the primary cellular mechanism underlying most of the effects of caffeine, including the mood and performance stimulant effects as well as the physiological effects and symptoms accompanying caffeine abstinence. Considerable data also suggest that the central stimulant effects of caffeine may be dopaminergically mediated (Ferre et al. 1997, Garrett and Griffiths 1997, Fredholm et al. 1999, 2005). More specifically, it is established that caffeine enhances dopaminergic activity by competitive antagonism of central adenosine receptors that are colocalized and functionally interact with dopamine receptors (Ferre et al. 1997, Fredholm et al. 1999, Ciruela et al. 2006). As a competitive antagonist at adenosine receptors, caffeine is believed to produce most of its low- to moderate-dose stimulant behavioral effects by removing the negative modulatory effects of adenosine from dopamine receptors, thus, stimulating dopaminergic activity (Ferre et al. 1997, Fredholm et al. 1999, Garrett and Griffiths 1997). Furthermore, dopamine release in the nucleus accumbens shell has been proposed as a specific neuropharmacological mechanism underlying the addictive potential of many drugs including the abused stimulants (Di Chiara and Bassareo, 2007), and in vivo microdialysis studies have shown an increase in dopamine release in the nucleus accumbens shell after local or systemic administration of caffeine (Solinas et al. 2002, Quarta et al. 2004a, Quarta et al. 2004b). The failure of some studies to reproduce these findings (Acquas et al. 2002, Quarta et al. 2004a) was shown to be related to a more restricted caffeine-responsive area in the nucleus accumbens shell (Borycz et al. 2007). Thus, although caffeine is a less efficacious behavioral stimulant than cocaine and amphetamine, it appears to share the common mechanism of increased dopaminergic activity with these classic stimulant drugs of abuse.

Treatment

In a survey of physicians’ practices, it was found that over 75% of medical specialists recommend that patients reduce or eliminate caffeine for certain conditions including anxiety, insomnia, arrhythmias, palpitations and tachycardia, esophagitis/hiatal hernia, and fibrocystic disease (Hughes et al. 1988). However, stopping caffeine use can be difficult for some people. For example, in a diagnostic study of caffeine dependence (Strain et al. 1994), subjects reported...
physical conditions such as acne rosacea, pregnancy, palpitations, and gastrointestinal problems that led physicians to recommend that they reduce or eliminate caffeine; all reported that they were unable to follow their doctor’s recommendations.

While there have been no systematic studies which have examined the treatment of people with a clearly established diagnosis of caffeine dependence, several studies with heavy caffeine consumers demonstrated efficacy of a structured caffeine reduction treatment program (i.e., caffeine fading) in achieving substantial reductions in caffeine consumption (James et al. 1985, 1988, Bernard et al. 1981, Foxx and Rubinoff 1979). These reports have generally noted success with a combination of gradual tapering of caffeine, self-monitoring of daily caffeine use, and reinforcement for decreased use. When attempting to reduce or eliminate caffeine use, several steps may be useful (Table 56–5). Since many individuals are not knowledgeable about sources of caffeine in their diets, education and history taking are likely to be important components of treatment. During caffeine tapering it may be useful for the patient to consume extra noncaffeinated fluids, to avoid herbal preparations which contain caffeine or other psychoactive drugs, to avoid the use of anxioytics, and to maintain a diary throughout the time they are progressively decreasing their caffeine use in order to monitor their progress. Abrupt cessation of caffeine should be avoided in order to minimize withdrawal symptoms and increase the likelihood of long-term compliance with the dietary change. No data about the probability of relapse is currently available, although relapse after caffeine reduction has been reported (James et al. 1988).

### Table 56–5  Method for Eliminating or Reducing Caffeine Use

<table>
<thead>
<tr>
<th>Step</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Educate patient about sources of caffeine. For example, some individuals might not be aware that caffeine is present in noncola soft drinks or analgesics.</td>
</tr>
<tr>
<td>2</td>
<td>Use a daily diary to have the person identify all sources of caffeine in their diet. Calculate the total milligrams of caffeine consumed on a daily basis. Self-monitoring should be continued during the reduction phase.</td>
</tr>
<tr>
<td>3</td>
<td>Determine a modification goal in collaboration with the patient. Some individuals may want to completely eliminate caffeine, while others may want to reduce their consumption. Individuals who want to reduce consumption but avoid withdrawal symptoms if they omit caffeine for a day should limit their intake to no more than 50 mg/day.</td>
</tr>
<tr>
<td>4</td>
<td>Generate a graded dose reduction (i.e., fading schedule) of caffeine use. Reasonable decreases would be 10–25% of the initial dose every few days. Allow for individualization of the caffeine fading. Rather than attempting to progressively eliminate consumption of the preferred caffeine beverage, it may be useful to suggest that the patient substitute decaffeinated for caffeinated beverages. In the case of coffee or tea, caffeine fading can be accomplished by mixing caffeinated and decaffeinated beverages together and progressively increasing the proportion of decaffeinated beverage.</td>
</tr>
<tr>
<td>5</td>
<td>Discuss the possibility of relapse with the patient. Discuss triggers (i.e., antecedent conditions) for caffeine use and offer coping strategies for high-risk relapse situations. Suggest that the patient continue to self-monitor caffeine consumption.</td>
</tr>

### Caffeine-Induced Anxiety Disorder

#### Diagnosis

**Definition and Diagnostic Features**

In addition to the symptom of anxiety that can be a component of caffeine intoxication, caffeine can also produce anxiety disorder, caffeine-induced anxiety disorder (American Psychiatric Association 2000) (see DSM-IV-TR criteria). Although there has been no work using this specific set of diagnostic criteria, the clinical features of the disorder have been described (Greden 1974, Uhde 1990) and there have been several studies examining the relationship between caffeine and anxiety in general, and this work is reviewed here.

Substance-induced anxiety disorders in general are distinguished by prominent anxiety symptoms that are
directly related to a psychoactive substance (American Psychiatric Association 2000). Whereas the form of the disorder can resemble panic disorder, generalized anxiety disorder, social phobia, or obsessive–compulsive disorder, a patient with a substance-induced anxiety disorder does not need to manifest all the diagnostic criteria of one of these conditions to justify making the diagnosis of a substance-induced anxiety disorder.

**DSM-IV-TR Criteria**

**Substance-Induced Anxiety Disorder**

A. Prominent anxiety, panic attacks, or obsessions or compulsions predominate in the clinical picture.

B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):

1. The symptoms in Criterion A developed during, or within 1 month of, substance intoxication or withdrawal
2. Medication use is etiologically related to the disturbance

C. The disturbance is not better accounted for by an anxiety disorder that is not substance induced. Evidence that the symptoms are better accounted for by an anxiety disorder that is not substance-induced might include the following: The symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication, or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence suggesting the existence of an independent nonsubstance-induced anxiety disorder (e.g., a history of recurrent nonsubstance-related episodes).

D. The disturbance does not occur exclusively during the course of a delirium.

E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Note: This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the anxiety symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the anxiety symptoms are sufficiently severe to warrant independent clinical attention.

**Assessment and Differential Diagnosis**

The diagnosis of caffeine-induced anxiety disorder is based on evidence of an anxiety disorder etiologically related to caffeine (see Figure 56–2 for the diagnostic decision tree). Other diagnoses to consider include caffeine intoxication, a primary anxiety disorder, and an anxiety disorder due to a general medical condition. Caffeine-induced anxiety disorder can occur in the context of caffeine intoxication, but the anxiety symptoms associated with the caffeine-induced anxiety disorder should be excessive relative to the anxiety seen in caffeine intoxication (American Psychiatric Association 2000). In addition to these conditions, substance-induced anxiety disorder can be produced by a variety of other psychoactive substances (e.g., cocaine).

**Epidemiology, Comorbidity and Course**

There are no specific data on the prevalence or incidence of caffeine-induced anxiety disorder, comorbid conditions or the natural history of caffeine-induced anxiety disorder.

**Etiology and Pathophysiology**

**Individual Differences and Genetic Factors**

Individual differences and genetic factors that contribute to caffeine-induced anxiety were discussed in the section on caffeine intoxication. As described below, individuals with anxiety disorders are particularly sensitive to the anxiogenic effects of caffeine.

**Neurobiological and Psychological Factors**

Caffeine's ability to produce anxiety has been studied in two populations: persons without an anxiety disorder, and those with an anxiety disorder. While these studies do not directly assess for a caffeine-induced anxiety disorder, they provide information about the relationship between anxiety and caffeine.

**Caffeine-Induced Anxiety in Normals**

Studies with volunteers that do not have an anxiety disorder show that acute doses of caffeine produce increased ratings of anxiety (Nickell and Uhde 1994, Griffiths et al. 2003). These effects are dose related, and high acute doses of oral and intravenous caffeine have been shown to produce panic attacks in persons without an anxiety disorder (Lin et al. 1997, Telch et al. 1996, Nickell and Uhde 1994). Thus, excessive acute caffeine consumption can mimic panic attacks, while chronic caffeine consumption can mimic generalized anxiety (Uhde 1990).

**Caffeine’s Anxiety-Inducing Effects in Persons With Anxiety Disorders**

Individuals with panic disorder report greater caffeine-induced anxiety than matched controls (Boulenger et al. 1984, Lee et al. 1985). Experimental studies show that caffeine exacerbates anxiety symptoms in individuals with generalized anxiety disorder (Bruce et al. 1992) and panic disorder (Beck and Berisford 1992, Charney et al. 1985) more than in control subjects. Interestingly, patients with anxiety disorders generally have lower levels of caffeine consumption than healthy controls (Rihs et al. 1996, Lee et al. 1985, 1988, Uhde 1990). This suggests that some people (such as patients with an anxiety disorder) may avoid caffeine use because of anxiety effects produced by caffeine.

Finally, it has also been shown that patients with high caffeine consumption have higher rates of anxiolytic use.
than patients with moderate or low caffeine use (Greden et al. 1981). This relationship does not appear to be reciprocal, as benzodiazepine users have levels of caffeine intake which are similar to nonusers (Cooper et al. 2004). It is not known whether some patients consume higher levels of caffeine to antagonize the sedative effects of minor tranquilizers, whether minor tranquilizers are prescribed in response to the anxiogenic effects produced by higher doses of caffeine (Roache and Griffiths 1987), or whether some underlying factors (e.g., personality) may account for the increased use of caffeine and anxiolytics together.

Pharmacological Mechanism of Action
As discussed in the prior sections on caffeine intoxication, caffeine withdrawal, and caffeine dependence, antagonism of the endogenous neuromodulator adenosine at adenosine receptors is the primary cellular mechanism underlying most of the effects of caffeine, including those related to the anxiety-inducing effects.

Treatment
Guidelines for treatment should generally follow those recommended for the treatment of caffeine dependence (see earlier). Thus, an initial, careful assessment of caffeine consumption should be conducted, and a program of gradual decreasing caffeine use should be instituted (see Table 56–5). Abrupt cessation of caffeine use should be avoided to minimize withdrawal symptoms and to increase the likelihood of long-term compliance with the dietary change. Given the etiological role of caffeine in caffeine-induced anxiety disorder, the prudent course of treatment would avoid the use of pharmacological agents such as benzodiazepines for the treatment of the anxiety disorder until caffeine use has been eliminated. A temporary caffeine-free trial may be useful in persuading skeptical patients about the role of caffeine in their anxiety symptoms. Bruce and Lader (1989) reported that instructions to stop all caffeine use for 1 week led to a significant improvement in more than half of individuals who presented for treatment at an anxiety clinic, with some requiring no further treatment.

Caffeine-Induced Sleep Disorder

Diagnosis

Definition and Diagnostic Features
Psychoactive substances can produce sleep disorders distinct from the sleep disturbances associated with intoxication or withdrawal produced by that substance (American Psychiatric Association 2000). It has long been recognized that caffeine-containing products can produce sleep disturbances, primarily in the form of insomnia. For example, Chavanne (1911) wrote that “black coffee will make some people lie awake and try to stare through the ceiling….” Although caffeine primarily produces insomnia, there are case reports of hypersomnia associated with acute use of caffeine (Regestein 1989).

The primary feature of a substance-induced sleep disorder is a sleep disturbance directly related to a psychoactive substance (see DSM-IV-TR Criteria) (American Psychiatric Association 2000). The form of the disorder can be insomnia, hypersomnia, parasomnia, or mixed, although caffeine typically produces insomnia. In general, sleep disturbance can often be a feature of substance intoxication or withdrawal (although sleep disturbance does not typically occur with caffeine withdrawal), and caffeine-induced sleep disorder should be diagnosed in patients who are having caffeine intoxication only if the symptoms of the sleep disturbance are excessive relative to what would typically be expected.

In addition to caffeine-induced sleep disorder, it is worth noting that complaints of poor sleep that are not severe enough to qualify as a “disorder” may also be related to caffeine use. It is not uncommon for patients to complain of sleep difficulties while failing to recognize the possible

role of caffeine ingestion in their complaints (Brown et al. 1995). A careful assessment of caffeine use, including time of use and quantity, should be included in the evaluation of a patient with sleep difficulties, even if these sleep problems do not constitute a sleep disorder.

Assessment and Differential Diagnosis
The diagnosis of a caffeine-induced sleep disorder is based on evidence of a sleep disorder etiologically related to caffeine (see Figure 56–2 for diagnostic decision tree). Other diagnoses to consider include caffeine intoxication and caffeine withdrawal, a primary sleep disorder, insomnia or hypersomnia related to another mental disorder, and a sleep disorder due to a general medical condition (American Psychiatric Association 2000). A caffeine-induced sleep disorder can occur in the context of caffeine intoxication or caffeine withdrawal, but the sleep symptoms associated with the caffeine-induced sleep disorder should be excessive relative to the sleep disturbance seen in caffeine intoxication or caffeine withdrawal (American Psychiatric Association 2000).

Although caffeine consumption may decrease with age, the elderly commonly report increased sleeping problems that may be exacerbated by caffeine (Curless et al. 1993). Occult caffeine consumption in the form of analgesic medication may produce sleep problems in the elderly (Brown et al. 1995). An association between disturbed sleep and caffeine consumption has been reported in adolescents (Pollak and Bright 2003, Orbeta et al. 2005).

As with caffeine-induced anxiety disorder, a trial of caffeine abstinence may be useful in confirming the diagnosis and helping to convince a skeptical patient about the etiological significance of caffeine in their sleep disorder.

Epidemiology and Comorbidity
There are no specific data on the prevalence, incidence, or comorbidity patterns of caffeine-induced sleep disorder.

Course
There is little information available on the course or natural history of caffeine-induced sleep disorder. Sleep disturbances due to caffeine are more likely to occur in people who are not regular caffeine consumers (Colton et al. 1968). In a study of caffeine use as a model of acute and chronic insomnia, subjects maintained on a high dose of caffeine (1200 mg/day) for 1 week demonstrated some adaptation to the sleep-altering effects of caffeine (Bonnet and Arand 1992). Thus, caffeine-induced sleep disorder may be a time-limited condition that reflects relatively acute responses to the effects of caffeine.

Beneficial Effects of Caffeine on Performance Degraded by Sleep Loss
Although caffeine can produce a sleep disorder, it should be noted that caffeine’s effects on sleep may also serve beneficial effects under certain circumstances. Numerous studies have demonstrated that caffeine can improve alertness and performance that have been degraded by sleep loss (Bonnet et al. 2005). In general, it appears that caffeine dose-dependently reverses the effects of 1–2 days of sleep deprivation. Compared to lower acute doses, 600 mg of caffeine shows greater efficacy in attenuating the effects of sleep deprivation over a several hour period of time, although lower doses of caffeine are not necessarily ineffective and may exert beneficial effects that are primarily shorter in duration (Reyner and Horne 2000). However, naps can also improve performance in sleep-deprived individuals, and combining caffeine with naps may be particularly effective in counteracting the effects of sleep deprivation (Reyner and Horne 1998, Bonnet et al. 1995).

Etiology and Pathophysiology
Caffeine-induced sleep disorder by definition is etiologically related to caffeine. Caffeine’s effects on sleep can depend on a variety of factors, such as the dose of caffeine ingested, the individual’s tolerance to caffeine, the time between caffeine ingestion and attempted sleep onset, and the ingestion of other psychoactive substances. The effects of caffeine on various measures of sleep quality are an increasing function of dose (Karacan et al. 1976, Hindmarch et al. 2000). Caffeine administered immediately prior to bedtime or throughout the day has been shown to delay onset of sleep and rapid eye-movement sleep, reduce total sleep time, alter the normal stages of sleep, and decrease the reported quality of sleep (Hindmarch et al. 2000, Goldstein 1964, Snel 1993). For example, in a study of subjects who consumed a capsule containing either placebo or 200 mg of caffeine before their usual bedtime, average time to sleep onset was 44 minutes after placebo and 77 minutes after caffeine (Goldstein 1964). Notably, for some subjects in this study, sleep onset after caffeine ingestion was delayed as long as 240 minutes. Although there is less evidence that caffeine consumption early in the day disrupts sleep, one study found that a single dose of 200 mg caffeine taken in the morning produced small but significant effects on the following night’s total sleep time, sleep efficiency and EEG power spectra (Landolt et al. 1995).

Individual Differences and Genetic Factors
Caffeine-induced sleep disturbance is greatest among individuals who are not regular caffeine users (Snel 1993, Colton et al. 1968). It is not known if this difference is due to acquired caffeine tolerance or to preexisting population differences in sensitivity to caffeine. Although some acquired tolerance to the sleep disrupting effects of caffeine has been demonstrated (Bonnet and Arand 1992), complete tolerance may not occur. Therefore, regular consumers of caffeine may still experience caffeine-induced sleep problems (Drapeau et al. 2006, Goldstein 1964, Goldstein et al. 1965). In addition to sleep disruption, studies have shown that caffeine withdrawal after acute abstinence from chronic caffeine can increase sleep duration and quality (Juliano and Griffiths 2004).

Genetic factors that contribute to individual differences in sensitivity to caffeine were discussed in the section on caffeine intoxication. Genetic variations of adenosine deaminase and an A2A receptor gene polymorphism have been shown to affect intensity and sleep architecture (Retey et al. 2005).

Pharmacological Mechanism of Action
As discussed in the prior sections on caffeine intoxication, caffeine withdrawal, and caffeine dependence, antagonism of the endogenous neuromodulator adenosine at adenosine
receptors is the primary cellular mechanism underlying most of the effects of caffeine, including those related to the sleep disrupting effects.

**Treatment**

There are no studies on the treatment of caffeine-induced sleep disorder. As for other conditions associated with caffeine use, such as caffeine dependence, caffeine intoxication, and caffeine-induced anxiety disorder, general guidelines for caffeine reduction can be recommended. These include an initial assessment of total caffeine consumption followed by a program of gradually decreasing caffeine use (see Table 56–5). Abrupt cessation of caffeine use should be avoided to minimize withdrawal symptoms and to increase the likelihood of long-term compliance with the dietary change. Given the etiological role of caffeine in caffeine-induced sleep disorder, the use of pharmacological agents or other interventions to improve sleep should be avoided until an adequate trial off caffeine establishes the presence of a noncaffeine-related sleep disorder.

**Conclusion**

Caffeine is the most widely consumed mood-altering drug in the world. In the United States, almost 90% of adults and children consume caffeine regularly. Habitual consumption of caffeinated soft drinks, coffee, or tea with meals is extremely common and may not be readily recognized as caffeine consumption. The cultural integration of caffeine use can make the identification of psychiatric disorders associated with caffeine use difficult. This chapter reviews five disorders associated with caffeine use (caffeine intoxication, caffeine withdrawal, caffeine dependence, caffeine-induced anxiety disorder, and caffeine-induced sleep disorder) and documents that the prevalence of caffeine-induced psychiatric syndromes is higher than may be commonly appreciated.

Introduction
Cannabis refers collectively to the psychoactive products of the hemp plants *Cannabis sativa* and *Cannabis indica*. Although it had previously been thought that only the female plant produces psychoactive agents, it is now known that the male plant also produces comparable amounts of the psychoactive substance, delta-9-tetrahydrocannabinol (THC). Cannabis products include: marijuana, which is the leaves, stems, and flowers of the plant; sinsemilla, which is just the flowering tops of the plant; and hashish, which is the sticky resin exuded by the plant. Although there are important differences between these products, convention holds that the term “marijuana” is used in place of the less specific “cannabis” in both common parlance and in the literature.

Epidemiology of Cannabis Abuse and Dependence
Cannabis is the most widely used illicit drug in the world, and in the United States. The World Health Organization estimated that during the 1990s, there were 141 million cannabis abusers worldwide, accounting for 2.5% of the world population (World Health Organization 1997). In the United States it is estimated that 25 million people (10.6%) aged 12 or older reported using marijuana in the past year. The Substance Abuse and Mental Health Service Administration (SAMHSA) further estimates that 3.1 million people (1.3% of the population) use marijuana daily (Substance Abuse and Mental Health Services Administration 2004). A conservative estimate is that 8% of people who try marijuana will develop cannabis dependence (Wagner and Anthony 2002). A recent study noted that rates of marijuana use among college students has trended upward, from 27.9% in 1993 to 33.3% in 2005 (The National Center on Addiction and Substance Abuse at Columbia University (CASA) 2007). While recent studies have shown that overall rates of marijuana use have been stable for the past decade, the rates of people suffering from marijuana abuse and dependence have increased slightly between the early 1990s and 2002, with the increase being statistically significant (Compton et al. 2004).

A Brief History of Cannabis
Eastern World
It is likely that cannabis originated in Central Asia and was cultivated extensively first in China, as far back as 10,000 BCE. It was later cultivated in India. The hemp plant was grown for its tough fiber, which was used in making cloth and ropes. In addition, seeds of the hemp plant were an important source of food and cooking oil (Iverson 2000). Cannabis was spread via trade from China and India to Persia. From Persia cannabis reached the Arab world, and the Arabs spread cultivation down the east coast of Africa (Courtwright 2001).
In addition to being a standard agricultural product, cannabis was also grown for its psychoactive properties. Cannabis was used in many traditional Chinese medicines as well as in traditional Indian ayurvedic remedies (Iversen 2000). It was also used as an intoxicant. In the mystical Islamic tradition, Sufism, rituals made use of the psychoactive properties of cannabis. Another famous group who used cannabis was the Hashishins (from which we get our word assassin), a group rumored to carry out killings while intoxicated with cannabis. While stories of this group have been used to the advantage of cannabis opponents, little is actually known about them or the role cannabis played in the activities of their group, for example, whether they used the drug to embolden them to commit murders, whether the drug was given to them by their superiors to keep them docile, or whether they used it in a manner similar to that of their contemporaries.

Western World
Cannabis was grown for fiber by the ancient Greeks, and was used to make the sails used by their navies. Cannabis continued to be cultivated through the time of the Romans. The Roman physicians Galen, Oribasius and Dioscorides wrote of the psychoactive properties of the cannabis plant (Iversen 2000). Cannabis was cultivated as a fiber crop throughout Europe, used in the production of ropes, sails and cloth. These products were widely used; in fact, our word canvas comes from the Dutch pronunciation of “cannabis” (Iversen 2000). Cannabis cultivation occurred in the Spanish, British, and French colonies in the Americas. While the slaves and lower classes that worked these plantations smoked cannabis for recreation, the ruling classes, gained counter-culture cache in the 1930s and 1940s and upper class America through the experience of the Beat writers, and later the “counter-culture” youth movement of the 1960s (Courtwright 1999). The use of cannabis was brought to middle class people in Egypt that Europeans became familiar with the psychoactive and intoxicating properties of these plants (Iversen 2000). Although European literati began smoking cannabis in the late 1800s, cannabis was principally used in patent medicines in the United States, rather than as an intoxicant per se. Cannabis, not being perceived as a problem of the magnitude of cocaine or opiates, was not included in the Harrison Act of 1914 (Musto 1999). Cannabis smoking was introduced in the United States by Mexican laborers who entered the country in the first decades of the 1900s (Courtwright 2001). Fueled in part by a concern about a novel intoxicant unfamiliar to mainstream American society, and propelled by racist caricatures of an intoxicated and dangerous ethnic “other,” cannabis was effectively outlawed in 1937. Cannabis smoking, popularized by jazz musicians, gained counter-culture cache in the 1930s and 1940s (Jonnes 1996). The use of cannabis was brought to middle and upper class America through the experience of the Beat writers, and later the “counter-culture” youth movement of the 1960s (Courtwright 1999).

Methods of Use
The most common method for using cannabis is smoking. One popular method for doing this is by using a pipe. These pipes can be made of metal, stone, glass, or other heat resistant materials. A bong is a specific kind of pipe that works by drawing the smoke through a layer of water, which both cools and removes tar from the smoke. Pipes and bongs come in an incredible array of colors, shapes and sizes. People who use these devices to smoke typically quantify their use in terms of the number of “bowls” they smoke.

Another popular way in which cannabis is smoked is by rolling it into cigarettes, or “joints.” More recently, the “joint” has increasingly given way to the “blunt.” A blunt is a cannabis cigar, named for a specific kind of widely available mass-produced cigar called a Phillies Blunt™. A blunt is made by slitting open a cigar wrapper, removing some or all of the tobacco within and replacing it with cannabis. The cigar is then resealed and smoked. To quantify use, we typically ask how many joints are smoked each day or each week. Our conversion, given the larger size of a cigar wrapper compared to a cigarette paper, is that one blunt is roughly equivalent to three joints. However, our experience has shown that the amount of cannabis placed in a joint or a blunt can vary considerably from person to person.

A third way cannabis is “smoked” is by using a vaporizer. A vaporizer works on the principle that THC volatilizes at a lower temperature than that at which cannabis combusts. Cannabis is electrically heated in a sealed glass container. When the THC volatilizes into a “vapor” and fills the chamber, this vapor is inhaled, theoretically obviating ingesting the carcinogens that arise from pyrolysis. Although the manufacturers of vaporizers have supported research that purportedly shows that these devices achieve this goal, there are no peer-reviewed data that support these claims.

Another way in which cannabis is used is by ingesting it. Given that THC is highly lipophilic, it readily leaves the plant and enters a substance like butter or oil when heated. This THC-laden butter or oil can then be used in the preparation of other foods, such as brownies (yielding the so-called “space cakes”). Cannabis can also be steeped as a tea.

Another common way cannabis is used is in hashish. Hashish is the purified resin produced by the cannabis plant, minus the actual plant material. Hashish is primarily made in one of two ways. The first way is from rolling cannabis plants between the palms of one’s hands. The sticky resin deposits itself on the skin, and this resin can then be scraped off and formed into larger lumps. The second method for making hashish comes from sieving cannabis through progressively finer sieves. The plant fibers are removed, and the resin remains, in a light powder form. This can then be heated and compressed into cakes. Hashish is typically smoked, but it can be eaten.

A final common way cannabis is used is in the production of cannabis oil, also known as hashish oil. This is usually formed by soaking cannabis plants in alcohol, which allows the lipophilic THC to enter the alcohol solution. The resulting supernatant can be heated or simply left to sit to allow the alcohol to evaporate. The sticky amber colored substance that remains is hashish oil. This product can be smoked, typically by placing a drop of oil onto heated metal and then using a straw to inhale the smoke that is produced.

Cannabis use can be quantified by a function of the frequency of use and the amount used. The amount used can be expressed as a functional unit of use (e.g., the number of “bowls,” joints, or blunts used in a given day or week) or in weight (e.g., a quarter ounce is used over a month). Another method for quantifying use is to ascertain how much money

is spent on use. Marijuana and sensimilla are typically sold in increments of $5 (“nickel bags”) or $10 (“dime bags”). The difficulty with this is that price varies with geography and quality of the product in ways that can be highly variable and difficult to predict.

The average potency of different cannabis products can be found in Table 57–1.

There are data supporting the contention that cannabis potencies are increasing (ElSohly et al. 2000). Some authors have noted that the issue of rising potency of cannabis is one that periodically recurs in the national dialogue, and that the issue is rendered moot as cannabis smokers will “autotitrate” or smoke to a desired level of intoxication irrespective of drug potency (Mikuriya and Aldrich 1998). However, it has been observed that rates of alcoholism increased after the widespread manufacture and sale of more potent distilled spirits (Courtwright 1999). It has been hypothesized that the small but detectable increase in the prevalence of cannabis dependence is due to the increased potency of the drug (Compton et al. 2004).

Neuropsychological Effects of Cannabis Use

There are a number of acute neuropsychological effects that result from smoking cannabis. These include problems with short-term memory, sustained and divided attention, and complex decision making (Ehrenreich et al. 1999, Pope et al. 1995, 1997, 2001, Pope 1996, Schwart et al. 1989, Solowij et al. 1991, Solowij et al. 1995). In addition, acute use of cannabis increased measures of impulsivity on a computerized task (Lane et al. 2005). Neuropsychological deficits are more apparent when high-potency cannabis products are used (Ramaekers et al. 2006). However, users who are tolerant to the effects of cannabis do not show neuropsychological deficits after acute use (Hart et al. 2001).

A number of authors have described an “amotivational syndrome” associated with cannabis use, characterized by a lack of motivation, ambition and direction in life (Kupfer et al. 1973, Campbell 1976, Hendin and Haas 1985). This syndrome appears to be the result of continuous intoxication and resolves with the cessation of cannabis use (Johns 2001). A study of chronic users showed that after a 28 day period of abstinence the user’s neuropsychological deficits resolved and they reported increased productivity and satisfaction in their work and social lives (Pope et al. 2001, Gruber et al. 2003). In summary, the intoxicating effects of cannabis can cause a number of neuropsychological deficits, these are less pronounced in tolerant individuals, they can lead to subjective complaints, and they resolve with abstinence.

Psychosocial Aspects of Cannabis Use and Related Disorders

Early exposure to cannabis has been demonstrated to be an independent risk factor for continued cannabis use, other drug use, juvenile offending and unemployment (Fergusson and Horwood 1997). Also, a significant relationship has been demonstrated between the degree of cannabis use and the likelihood to commit certain violent crimes (Friedman et al. 2003). Further, an association between cannabis use and risky sexual behavior has been found (Kingree et al. 2000, Kingree and Betz 2003). For those individuals that develop cannabis dependence, the consequences of their addiction are as serious as those of addictions to other illicit drugs. The medical, legal, and psychiatric impairment associated with cannabis dependence appears roughly comparable to that of cocaine dependence (Budney et al. 1998).

A common notion is that cannabis is a “gateway drug” whose use leads in some causal fashion to the use of other, “harder” drugs. In support of this it has been noted that among adolescents cannabis use comes temporally before the use of harder drugs (Yamaguchi and Kandel 1984, Yamaguchi and Kandel 1984). However, temporal precedence does not imply causality. It is likely that adolescents who choose to use cannabis in the first place are more socially marginalized and exhibit behavioral problems compared to those who do not, and that those who use cannabis early tend to affiliate with more delinquent peers (Fergusson and Horwood 1997).

Endocannabinoid System

Two subtypes of cannabinoid receptors have been identified so far. The first, the CB1 receptor, is expressed on the axons, terminals, and somata of neurons. The second, the CB2 receptor, is expressed primarily on immune cells. CB1 receptor is abundant in the brain, more so than opioid or dopamine receptors, and are dense in the striatum, globus pallidus, substantia nigra, hippocampus and cerebellum (Rodriguez de Fonseca et al. 2005). Both CB1 and CB2 receptors are coupled to inhibitory G proteins and inhibit adenylyl cyclase and active MAP kinase. In addition, CB1 receptors inhibit presynaptic calcium channels of the N and P/Q type and activate inwardly rectifying potassium channels. This receptor subtype also affects a number of other signaling mechanisms. There are likely to be other cannabinoid receptors that have yet to be identified (Mackie 2006). THC seems to function as a partial agonist at the CB1 and CB2 receptors (Mackie 2006).

There are a number of endogenous substances that bind to these receptors. These endocannabinoids are derivatives of arachadonic acid. The first of these to be identified is anandamide, whose name comes from Sanskrit for “internal bliss.” In addition there is 2-arachidonoylglycerol (2-AG), virodhamine, and nolandin (Rodriguez de Fonseca et al. 2005). The endocannabinoid system seems to modulate neuronal plasticity, and function to preserve the structure and function of major brain circuits. This is important for homeostatic behavior such as eating, sleeping, reproducing and relaxing and other motivated behaviors. In addition, endocannabinoids modulate the immune system, vascular...
The endocannabinoid system also appears to play a role in maintaining emotional homeostasis, for example by facilitating the extinction of aversive memories (Marsicano et al. 2002).

Activation of the mesocorticolimbic dopamine system has been implicated in reinforcing drug-taking behavior (Koob 1992). The cell bodies of this system originate in the ventral tegmental area and project to forebrain areas, including the nucleus accumbens (Koob 1992). THC has been shown to increase dopamine release in the nucleus accumbens (Tanda et al. 1997). Although cannabinoids have been shown to interact with a number of neurotransmitter systems including the GABAergic, glutamtergic, and cholinergic systems, its interactions with this dopaminergic system and with the opioid system is thought of be of primary importance in facilitating dependence (Tanda and Goldberg 2003).

### Cannabis Related DSM-IV-TR Diagnoses

#### Cannabis Intoxication

The most elemental cannabis related diagnosis is that of intoxication. In order to make this diagnosis (see DSM-IV-TR Criteria 292.89) the patient must have used cannabis recently and be having some psychological or behavioral change as a result. In addition a person must be experiencing two of the following four signs and symptoms: conjunctival injection, increased appetite, dry mouth, and tachycardia. The symptoms also cannot be better accounted for by another medical or mental condition. There is also a specifier, “with perceptual disturbances” if the intoxicated individual is experiencing illusions or hallucinations without losing reality testing or being delirious.

In addition, there are a number of other physiological and psychological effects of cannabis described in the literature that do not appear in the DSM. These are listed in Table 57–2. (Hall and Solowij 1998, Ameri 1999, Perez-Reyes 1999).

#### Cannabis Abuse

Criteria for cannabis abuse (see DSM-IV-TR Criteria 305.20) are met when an individual’s cannabis use persists despite adversely affecting his or her life. To be diagnosed with Cannabis Abuse, over a 12-month period as a function of cannabis use an individual must have any one of the following: recurrent episodes of failing to fulfill obligations at work, school, or home; recurrent episodes of cannabis use when using results in physical danger; recurrent legal difficulties; or recurrent arguments or disputes with others. A simple mnemonic device to remember these criteria is “FOLD” (see DSM-IV-TR Criteria 305.20): for Fights

---

### DSM-IV-TR Criteria

#### Cannabis Intoxication

A. Recent use of cannabis

B. Clinically significant maladaptive behavioral or psychological changes (e.g., impaired motor coordination, euphoria, anxiety, sensation of slowed time, impaired judgment, social withdrawal) that developed during or shortly after cannabis use.

C. Two (or more) of the following signs, developing within 2 hr of cannabis use:

1. conjunctival injection
2. increased appetite
3. dry mouth
4. tachycardia

D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder.

**Specify if:** With Perceptual Disturbances: This specifier may be noted when hallucinations with intact reality testing or auditory, visual, or tactile illusions occur in the absence of a delirium. Intact reality testing means that the person knows that the hallucinations are induced by the substance and do not represent external reality. When hallucinations occur in the absence of intact reality testing, a diagnosis of Substance-Induced Psychotic Disorder, With Hallucinations should be considered.

Cannabis Abuse

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions or expulsions from school; neglect of children or household)
2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for Substance Dependence for this class of substance.

Mnemonic:
- Fights (social and interpersonal problems) — from criterion 4
- Obligations — from criterion 1
- Legal problems — from criterion 3
- Anger — from criterion 2

Cannabis Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
   a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect
   b. Markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal, as manifested by either of the following:
   c. The characteristic withdrawal syndrome for the substance
   d. The same (or a closely related) substance is taken to relieve or avoid the withdrawal syndrome
3. The substance is taken in larger amounts or over a longer period than was intended
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects
6. Important social, occupational, or recreational activities are given up or reduced because of substance use
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Mnemonic:
- Withdrawal — from criterion 2
- Health problems — from criterion 7
- Amount has increased — from criterion 3
- Tolerance — from criterion 1
- Cut down — from criterion 4
- Activities given up — from criterion 6
- Time pursuing drug has increased — from criterion 3

12-month period: Tolerance; withdrawal; using more cannabis or over a longer period of time than intended; there is a persistent desire to cut down or control one's use; an increasing amount of one's time is spent in the pursuit, use, and recovery from using cannabis; important activities are
given up or reduced because of cannabis; or cannabis use is continued despite ongoing mental or physical health problems which are caused or exacerbated by cannabis use.

Although the DSM-IV-TR and earlier editions do not recognize the diagnosis of cannabis withdrawal there is a well-characterized withdrawal state demonstrated in cannabis dependent individuals when the drug is removed. Cannabis withdrawal is characterized by anxiety, irritability, decreased mood and food intake, and physical discomfort (Haney et al. 1999a, 1999b, Kouri and Pope 2000). Most treatment-seeking cannabis-dependent patients report cannabis withdrawal symptoms, and these symptoms tend to be more severe in heavier users (Budney et al. 1999). It is important to note that physiological dependence (comprised of tolerance and/or withdrawal) is neither necessary nor sufficient to diagnose the dependence syndrome. A useful mnemonic for remembering these criteria is WHAT CAT (see DSM-IV-TR Criteria 304.3): Withdrawal, Health Problems, Amount has increased, Tolerance, desire to Cut down, Activities given up, Time spent use has increased. The validity of the concept of cannabis dependence has been shown to be equivalent to that of alcohol, opiate, stimulant and sedative dependences (Morgenstern et al. 1994).

Cannabis Intoxication Delirium

We have been unable to locate any reports of this diagnostic entity despite its inclusion in the DSM (see DSM-IV-TR Criteria 292.81). There are a number of reports of acute onset of a “toxic psychosis” of confusion, memory problems and hallucinations after using cannabis (Talbott and Teague 1969, Tennant and Groesbeck 1972, Chopra and Smith 1974, Chaudry 1991, Andre et al. 2006). However, these reports either pre-date the clinical entity of Cannabis Intoxication Delirium or insufficient clinical material is presented to ascertain if this is the best diagnostic label for the condition described. Interestingly, two of the most recent descriptions of toxic confusion in the literature both involve cases where cannabis was ingested rather than smoked (Chopra and Smith 1974, Chaudry et al. 1991). It seems possible that, given the slower onset of action of THC when ingested rather than smoked, it is more difficult to “autotitrate” (Mikuriya and Aldrich 1998) to the desired level of intoxication when ingesting rather than smoking cannabis, leading users to “overshoot the mark.” Regardless, given the widespread use of cannabis and the relative paucity of reports of cannabis intoxication delirium, we conclude that this must be a rare clinical entity. If this diagnosis is suspected, other causes of delirium should be aggressively excluded, especially if the delirium doesn’t resolve in a week (Johns 2001).

Cannabis-Induced Psychotic Disorder

There has long been an observed link between cannabis use and psychotic illness. Fifteen percent of cannabis users report having had some psychotic symptoms after having used cannabis (Thomas 1996). This tends to remit with the resolution of intoxication (Hall and Solowij 1998). The diagnostic criteria for Cannabis-Induced Psychotic Disorder is listed below (see DSM-IV-TR Criteria (With Delusions 292.11, With Hallucinations 292.12)) Some investigators believe that cannabis use has been shown to be an independent risk factor for the development of psychotic illnesses (Arseneault et al. 2004, Henquet et al. 2005). However, there is no evidence that heavy cannabis use leads to a psychotic illness that persists after abstinence (Johns 2001). There is little evidence to support the contention that cannabis-induced psychotic disorders arise in previously asymptomatic individuals (Thomas 1993). If psychotic symptoms persist for more than 24-48 hr after intoxication they are likely referable to a previously undiagnosed psychiatric disorder (Johns 2001, Gruber and Pope 1994).

**DSM-IV-TR Criteria**

**Cannabis Intoxication Delirium**

A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.

B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.

C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

D. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):

1. the symptoms in Criteria A and B developed during Cannabis Intoxication

2. medication use is etiologically related to the disturbance

**Cannabis-Induced Psychotic Disorder**

A. Prominent hallucinations or delusions. Note: Do not include hallucinations if the person has insight that they are substance induced.

B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2):

1. the symptom in Criterion A developed during, or within a month of, Substance Intoxication

2. medication use is etiologically related to the disturbance
Chapter 57 • Substance Abuse: Cannabis-Related Disorders

Cannabis-Induced Anxiety Disorder

The most commonly reported adverse reaction to cannabis is acute anxiety or panic attacks (Hall and Solowij 1998, Johns 2001, Thomas 1996). This is particularly common among women and infrequent or naive users of cannabis (Hall and Solowij 1998, Thomas 1996). The mind-set of the user and the setting in which the use takes place therefore likely contribute to the effect of the drug to produce these anxiety reactions. The DSM-IV-TR provides criteria for the diagnosis of Cannabis-Induced Anxiety Disorder (see DSM-IV-TR Criteria 292.89). We have been unable to find reports of de novo onset of a true Cannabis Induced Anxiety Disorder in an individual without a preexisting Axis I mental illness. In a given individual, anxiety or panic that lasts longer than several days is likely due to an underlying psychiatric disorder (Johns 2001).

DSM-IV-TR Criteria

Cannabis-Induced Anxiety Disorder

A. Prominent anxiety, Panic Attacks, or obsessions or compulsions predominate in the clinical picture.

B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2): There is evidence from the history, physical

Treatment of Cannabis Related Disorders

Psychotherapy Trials

A variety of psychosocial interventions have been studied in cannabis dependence (see Table 57–3). Early work in treating cannabis dependence was based on anecdotal experience and advocated exercise, eating well, pulmonary care, treating insomnia, conducting a behavioral assessment, and 12-step programs (Zweben and O’Connell 1988, Miller et al. 1989). Other early work included open studies described treatments for cannabis dependence using aversion therapy with emetic agents (Morakinyo 1983) and electric shock (Smith et al. 1988).

A later uncontrolled study described an “integrated brief intervention” for marijuana dependence (Lang et al. 2000).

</table>
This intervention consisted of a 2.5-hr assessment and intervention that provided education and use-reduction strategies along with a self-help booklet. At 1- and 3-month follow-up the investigators found that the mean number of days during which marijuana was used decreased, the amount of marijuana used decreased and that subjects reported fewer “problems,” but it was not reported whether these differences were statistically significant.

The feasibility of a brief intervention for adolescent cannabis users was studied by Martin et al. (Martin et al. 2005) This open trial enrolled 73 adolescent cannabis users in a brief intervention based on the Marijuana Check-up (Stephens et al. 2004). The Adolescent Cannabis Check-up consists of one session of education for the teen’s parent, two sessions for assessment and feedback for the teen, and then an optional session of cognitive behavioral therapy. Follow-up obtained 3 months after the intervention showed significant reductions from baseline in both quantity and frequency of cannabis use as well as in the proportion of subjects qualifying for dependence diagnoses. Repeat follow-up at 6 months revealed significant reductions from baseline in both number of days of use and in the number of dependence symptoms subjects endorsed.

A number of randomized controlled trials of various psychotherapies have also been performed. Stephens, Roffman, and Simpson adapted the relapse prevention model of Marlatt and Gordon to treat marijuana dependence (Stephens et al. 1994). They randomized 212 treatment-seeking marijuana users to 10 two-hr group therapy sessions of either relapse prevention or social support therapy. The subjects were reassessed at 1, 3, 6, 9, and 12-month follow-up and had booster group therapy sessions at three and 6 months. The investigators found that both groups significantly reduced the amount and frequency of marijuana use and had fewer marijuana-associated problems, but neither treatment showed an advantage over the other.

Stephens, Roffman, and Curtin performed a second trial with relapse prevention to compare extended treatments to brief treatments (Stephens et al. 2000). Two hundred ninety one treatment-seeking individuals who frequently used marijuana were randomized to 14 sessions of a relapse prevention and social support group, two sessions of an individualized assessment and intervention that included motivation enhancement and cognitive-behavioral techniques focused on stopping marijuana use, or a delayed treatment control group. The investigators reported that up to 16 months after the intervention, compared to the control group both of the therapy groups had significantly reduced their marijuana use in terms of the number of days and the amount of marijuana used per day and experienced fewer depressive symptoms. Interestingly, neither the extended nor the brief treatment was more successful than the other for any outcome measure.

A second study investigating the effect of treatment duration recruited 229 outpatients who had stated a desire to reduce cannabis use and randomized them to a single session of cognitive behavioral therapy, six sessions of cognitive behavioral therapy, or a delayed control group (Copeland et al. 2001). The subjects were reassessed at 24 weeks after treatment conclusion. Neither treatment group had significantly more days of abstinence or percentage of subjects who maintained continuous abstinence compared to each other or the control group. However, subjects in both CBT groups were equally likely to report complete abstinence during the month prior to the follow-up and have fewer cannabis-related problems compared to the control group. The six session CBT group did show a small advantage compared to the one session CBT group in that, on average, they reported less cannabis consumption and had lower scores on the Severity of Dependence Scale.

Budney et al. performed a randomized study investigating the effect of the addition of vouchers to therapies for marijuana dependence (Budney et al. 2000). The investigators enrolled 60 subjects, all of whom met criteria for marijuana dependence, and randomized them to: (1) four 90-min sessions of motivational enhancement therapy (M), (2) Fourteen 60-min sessions of motivation enhancement plus behavioral coping skills training (MBT), or (3) MBT plus a voucher program (MBTV) using vouchers with a cash value for negative urine toxicology screens. They reported that the MBT and M groups showed reductions in a number of marijuana-related symptom scores, but did not differ from each other with respect to levels of actual marijuana use. However, the MBTV group had significantly more and longer periods of continuous abstinence compared with the other two treatment conditions. The subjects in the voucher group were also significantly more likely to be abstinent at the end of the study compared to the other two groups.

This same group recently published the results of a follow-up study of the use of vouchers in therapy for cannabis dependence (Budney et al. 2006). In this 14-week study, 90 treatment-seeking adults who met criteria for cannabis dependence were randomly assigned to one of three conditions: (1) Abstinence-based vouchers only (V), where participants received vouchers with a monetary value for each marijuana-free urine toxicology screen but didn’t receive therapy apart from a self-help pamphlet, (2) Cognitive-behavioral therapy (CBT), which consisted of 14 weekly therapy sessions. Vouchers were given for urine toxicology screens were also collected in this condition, but the value was the same irrespective of the presence or absence of evidence of marijuana use, and (3) CBT plus abstinence-based vouchers (CBT+V), which added the voucher program of the V group to the course of psychotherapy received by the CBT group.

At the end of treatment, participants in the voucher group had significantly more abstinence from marijuana than the participants in the CBT-only group. There were no significant differences in the abstinence rates between CBT+V and V, suggesting that CBT did not enhance the effect of the voucher program during treatment. Over the 12 months of follow-up, the CBT+V group had significantly greater abstinence rates than the CBT only group, but not the V group. However, significantly higher remission levels, defined as meeting no DSM-IV-TR dependence criteria, were observed in the CBT+V group compared to the V only group. These results imply that a voucher-only program was effective in producing continuous abstinence during the time the vouchers were offered (i.e. during treatment). However, after treatment ended cognitive behavioral therapy helped maintain the early gains facilitated by a voucher system.

To date, the largest therapy trial targeting cannabis dependence is the Cannabis Youth Treatment (CYT) study. This study randomized 600 adolescent users to one of five
different types of psychosocial interventions (Dennis et al. 2002, Diamond et al. 2002, Dennis et al. 2004, French et al. 2002). As described in our recent review paper (Nordstrom and Levin 2007) the five treatments tested were: (1) five sessions that included two motivational enhancement therapy and three cognitive behavioral therapy sessions (MET/CBT5), (2) twelve sessions that included two motivational enhancement therapy and ten cognitive therapy sessions (MET/CBT12), (3) family support network (FSN), a multi-component treatment designed to be added to MET/CBT12, (4) the adolescent community reinforcement approach (ACRA) that is comprised of 10 individual sessions and four sessions with the caregivers to educate them how to support the adolescent’s abstinence, and (5) twelve sessions of a multidimensional family therapy (MDFT) which is a family-focused therapy designed to work individually with adolescents and their families.

The CYT study was performed as two separate clinical trials. The “incremental” trial compared the three treatments that increase in intensity in a stepwise fashion: MET/CBT5, MET/CBT12, and FSN (which is added to MET/CBT12). The “alternative” trial compared treatments which varied in both type and length: MET/CBT5, ACRA, and MDFT. Follow-up data were obtained at three, six, nine, and 12 months. The two clinical outcomes were: (1) days of abstinence between the randomization date and the 12-month follow-up interview and (2) whether the adolescent was in recovery (defined as reporting no substance use, abuse, or dependence problems while living in the community) at the end of the study. The team reported that in both the incremental and alternative trials each treatment condition increased the number of subjects in recovery and days of abstinence, but that in neither trial did any one treatment show greater effectiveness than any other.

Another recent, large, multisite trial is the Marijuana Treatment Project (MTP) (Stephens et al. 2002, Steinberg et al. 2002, Marijuana Treatment Project Research G 2004). The MTP evaluated 450 cannabis dependent subjects were randomized to one of three treatment arms: (1) a two-session motivational enhancement intervention, (2) a nine-session treatment that added cognitive behavioral therapy and case management to the motivational enhancement sessions, and (3) a delayed treatment control group. The investigators gathered self and collateral report data at four and 9-month follow up periods, and performed a brief self-report phone check-in at 15 months. The investigators found that both treatment groups had comparable rates of improvement that were larger than those seen in the control group. Also, at the four and 15-month follow-up (but not the 9-month follow-up) the group that had the longer course of therapy was more likely to report being abstinence than the group that had a shorter course of therapy, which, in turn, was more likely to report being abstinent than the control group. Although it is unclear why the differences in abstinence between groups dissipated at 9 months and then reappeared at 15 months, this finding might be due to the lower standard used to ascertain abstinence at the 15-month follow-up (i.e. no urine was collected at that time point).

Three main findings arise from considering the studies of psychotherapy for cannabis dependence: (1) a number of psychotherapies have been shown to be helpful in the treatment of this disorder (2) with the exception of using vouchers alone or adding them to another therapy (Budney et al. 2000, Budney et al. 2006) no form of psychotherapy performs robustly better than any other (3) longer psychotherapies do not appear to be more advantageous than shorter therapies.

Pharmacologic Trials

A number of pharmacologic agents have been studied for their potential as treatments of cannabis dependence (Table 57–4). The majority of these studies have been performed in the laboratory setting with nontreatment seeking research participants. Comparably fewer trials have been performed in clinical settings for patients with cannabis dependence with or without psychiatric co-morbidity.

Pharmacotherapy in Cannabis Self Administration or Intoxication

One laboratory study investigated the effects of naltrexone when given with oral THC in heavy marijuana smokers (Haney et al. 2003). Compared to placebo, pretreatment with naltrexone was shown to significantly increase high-dose oral THC’s effects on a number of ratings of feeling “high,” and this effect was attained without raising serum THC levels.

The CB-1 selective antagonist SR141716 (now known as Rimonabant) has been shown to decrease ratings of marijuana drug effect in a dose-dependent fashion (Huestis et al. 2001). The investigators found that a 90 mg dose of Rimonabant taken before cannabis was smoked reduced both subjective drug effects and objective drug effects. Of note, the dose of Rimonabant used in clinical trials for the treatment of obesity was 20 mg a day (Van Gaal et al. 2005). The impact of Rimonabant on cannabis self-administration has not been published, and it is unclear if the effects described would lead to clinically meaningful reductions in cannabis use. Specifically, it is uncertain whether treatment-seeking THC-dependent individuals would adhere to a regimen of a CB-1 antagonist given that compliance is such a notable problem with naltrexone for the treatment of opiate dependence (Kosten and Kleber 1984, Kleber 1985). The use of cannabinoid receptor antagonists may require the implementation of additional psychosocial treatment approaches to enhance compliance.

In addition to cannabinoid antagonists, agonists have also been studies in cannabis use. Hart et al. investigated the effect of oral THC on marijuana self-administration (Hart et al. 2002). The investigators found that by the third day of maintenance with oral THC, subjects reported that the positive subjective effects of marijuana were reduced, although this did not affect their choice to self-administer marijuana.

Pharmacotherapy in Cannabis Withdrawal

A number of laboratory studies have been conducted investigating the effects of pharmacotherapeutic agents on cannabis withdrawal. Haney et al. also reported on the use of oral THC replacement therapy in attenuating marijuana withdrawal under experimental conditions (Haney et al. 2004). Compared to placebo, oral THC decreased ratings of anxiety, sleep difficulty, feeling “miserable,” “chills” and marijuana craving and reversed decreases in food intake. Oral THC did not affect ratings of irritability or social

</table>
withdrawal. Of note, no intoxication was produced with oral THC, with doses up to 10 mg, five times a day, in this heavy cannabis-using group.

Haney et al. studied the use of bupropion in marijuana withdrawal (Haney et al. 2001). The investigators found that compared to placebo, maintenance on bupropion worsened measures of mood and self-reported sleep quality during experimentally induced marijuana withdrawal. Another antidepressant that has been studied in marijuana withdrawal is nefazodone (Haney et al. 2003). Nefazodone was shown to decrease ratings of anxiety and muscle pain, but not irritability, malaise or poor sleep quality, during cannabis withdrawal.

Divalproex sodium was also investigated for utility in cannabis withdrawal (Haney et al. 2004). During experimentally induced abstinence, compared to placebo, divalproex sodium decreased marijuana craving but increased ratings of anxiety, irritability and tiredness.

**Pharmacotherapy in Cannabis Dependence**

There has been one published pharmacologic treatment trial that has specifically targeted cannabis dependence (Levin et al. 2004). Levin et al. performed a randomized controlled double-blind study in which 25 subjects who met DSM-IV-TR criteria for cannabis dependence were randomized to either divalproex sodium (dosed to blood levels between 50 ng/ml and 120 ng/ml) or placebo. At the end of the six-week trial there were no differences between the divalproex sodium and placebo groups, with few individuals achieving abstinence.

Another randomized, controlled double-blind study examined the use of bupropion and nefazodone in cannabis dependence (McDowell et al. 2006). In this study of 130 treatment-seeking cannabis-dependent individuals were randomized to either placebo, bupropion 300 mg/day or nefazodone 600 mg/day. At study end, neither medication was significantly more effective than placebo in either initiating abstinence from cannabis or alleviating the symptoms of cannabis withdrawal.

**Pharmacotherapy in Dual Diagnosis**

A number of trials have indirectly investigated the input of pharmacologic interventions in cannabis abusing individuals with comorbid psychiatric illness. Geller studied the use of lithium in bipolar adolescents with substance use disorders (Geller et al. 1992, 1998). Of the 25 subjects enrolled in the randomized placebo-controlled trials, 64% were dependent on either marijuana and alcohol or marijuana alone. Over the study there were significantly fewer positive urine toxicology screens for the lithium group compared to the placebo group. The utility of lithium to specifically decrease marijuana use was not presented. Interestingly, there are preclinical data demonstrating that lithium can attenuate cannabis withdrawal in rats, perhaps by modulating oxytocinergic activity (Cui et al. 2001), raising the possibility that lithium might be worthy of further study in THC-dependent individuals.

Riggs et al. carried out a randomized placebo-controlled trial of pemoline in a group of adolescents with attention-deficit/hyperactivity disorder (ADHD) and comorbid substance use disorders (Riggs et al. 2004). In this sample, 74% of the subjects were dependent on cannabis. Compared to placebo, the investigators found that pemoline attenuated the symptoms of ADHD but did not change substance use as measured by the number of positive urine toxicology screens or in the number of days drugs were used in the past month. In this study as well, the specific effects on cannabis relative to other drugs of abuse were not described.

In another study, Cornelius et al. conducted a secondary analysis of a randomized placebo-controlled trial of fluoxetine in a group of 22 depressed alcoholic inpatients that also met DSM-III-R criteria for marijuana dependence (Cornelius et al. 1999). Among the cannabis dependent patients, the fluoxetine and placebo groups did not differ in the amount or frequency of marijuana use prior to admission. During the 12 weeks of the study there was a significant group-time effect on marijuana use, and the cumulative number of marijuana cigarettes smoked over the study was 20 times higher in the placebo group compared to the fluoxetine group.

A number of factors limit the conclusions that can be drawn regarding the use of pharmacologic agents in the treatment of cannabis dependence. The first is that existing studies all had small sample sizes. Second, to date only two clinical trials have specifically targeted cannabis dependence (Levin et al. 2004, McDowell et al. 2006). Third, while some medications have shown promise in laboratory studies it is unclear if they would be useful in clinical settings. Medications that attenuate the intoxicating effects of cannabis or that lessen the symptoms of withdrawal could potentially be of use in initiating abstinence from cannabis. Medications that block the psychoactive effects of cannabis, decrease drug craving, or improve psychiatric symptoms might be of use in the prevention of relapse once initial abstinence has been attained.

**Conclusion**

Cannabis has a long history of use for its psychoactive properties but is a relative newcomer to the Western world as an intoxicant. Nowadays cannabis is widely used and it causes serious problems in a minority of those who use it. However, given the large numbers of people who use cannabis, that relative minority translates into a substantial population of problem users. Given this reality, clinicians need tools in their armamentarium with which to treat cannabis-use disorders. There are a number of psychotherapies that have proven to be effective for the treatment of cannabis-related disorders. So far, no medications have been found to be effective for the treatment of these maladies. However, as clinical trials continue and as we further our understanding of the endocannabinoid system useful medications will likely be developed.

Introduction
Cocaine is a central nervous system stimulant produced from the coca plant. Coca has been grown in the Andean Region of South America since 3000 BC. In 1860, cocaine was first synthesized from the dried Peruvian coca leaf in a German laboratory. In the 1960s cocaine became an extensively used illicit drug, with heaviest consumption in the United States, Canada, and Latin America. Cocaine is consumed in several preparations. Cocaine hydrochloride powder is usually snorted through the nostrils, or it may be mixed in water and injected intravenously. Cocaine hydrochloride powder is also commonly heated (cooked up) with ammonia or baking soda and water to remove the hydrochloride, thus forming a gel-like substance that can be smoked (freebasing). “Crack” cocaine is a precooked form of cocaine alkaloid that became popular in the 1980s. It is sold on the street as small “rocks.” Abundant supplies and relatively low prices for cocaine (the equivalent of 1 g of cocaine can be purchased for as little as $25–$50 and a vial of crack (two or three small rocks) can be had for about $10) have contributed to the prevalence of cocaine abuse and dependence as well as other related cocaine use disorders.

Epidemiology
The National Household Survey on Drug Abuse (NHSDA) reported that in 2005, 2.4 million Americans were current cocaine users with 1.5 million classified as cocaine abusers (SAMHSA 2005). Since 1975, the Monitoring the Future (MTF) study has annually examined the extent of drug abuse among 8th–12th graders. Use of cocaine decreased significantly among 12th graders, from 6.2% in 1999 to 5.0% in 2000; crack cocaine use in 2000 decreased from 2.7% to 2.2% for 12th graders. This was the first decrease in cocaine and crack cocaine use among 12th graders since the early 1990s. Crack use by 8th graders also decreased from a 10-year high of 2.1% in 1998 to 1.8% in 1999, which remained constant in 2000 (Johnson et al. 2001). While cocaine use has shown a downward trend, several statistics indicate that cocaine abuse is still a serious threat to the public. For example, cocaine-related emergency department visits constituted 29% of all drug-related visits in 2000, more than for any other illicit substance (SAMHSA 2001b). The National Drug Threat Assessment 2001 (National Drug Threat Assessment 2001—The Domestic Perspective, by the National Drug Intelligence Center, NDIC) reported that availability and demand for cocaine continues to be high.

Gender Differences in Cocaine Use Disorders
While men continue to have a higher rate of current cocaine use than women, the gap is narrowing (SAMHSA 2005). Cocaine use in women has been steadily rising for the past three decades. For example, for those born during 1946–1950 versus those born during 1966–1977, the male-to-female ratio for cocaine use at age 35 declined from 2.8 to 1.4. For those born in the years 1971–1975, cocaine use in early teenage years was actually more common in females than in males (SAMHSA 1996).
Some studies have reported that women cocaine abusers differ from men in several respects, including response to the direct administration of cocaine (Kosten et al. 1993, Kosten et al. 1996, Lukas et al. 1996, McCance-Katz et al. 2001). One study that examined responses to intranasal cocaine use in casual cocaine users reported that men have more rapid onset of effects and more intense drug effects than did women (Lukas et al. 1996). Another study using higher doses of cocaine administered nasally reported more anxiety in women (Kosten et al. 1996). One study reporting on the effects of administration of repeated doses of intranasal cocaine showed that women reported greater ratings of perception of overall mental and physical well-being than did men (McCance-Katz et al. 2001, McCance-Katz et al. 2005). However, several studies have found no significant differences in responses for men and women when given intravenous (Mendelson et al. 1999) or intranasal (Collins et al. 2006) cocaine. Yet, neuroimaging studies utilizing single photon emission computed tomography (SPECT) have shown that cocaine-dependent women had fewer perfusion abnormalities (Chang et al. 1999, Gottschalk et al. 2001, Levin et al. 1994) and less frontal cortex neuronal loss than men with comparable cocaine use history (Chang et al. 1999, Kaufman et al. 2001). Another neuroimaging study found that regional cerebral blood flow between abstinent cocaine-dependent men and women differed in the medial and orbitofrontal cortex which may lead to a better understanding of different relapse characteristics between men and women (Adinoff et al. 2006). Another study performed in abstinent cocaine-dependent individuals found fewer EEG abnormalities in women when compared to men (King et al. 2000).

Much of the research on substance abuse treatment efficacy is based predominantly on male samples. However, nearly 4% of pregnant women and 10% of women who were not pregnant reported use of an illicit drug in the past month (SAMHSA 2005) and women represented about 38% of substance abuse treatment admissions during 2004–2005 (SAMHSA 2005). Cocaine dependence in women is as severe as that in men, however women often receive less treatment for their substance abuse (McCance-Katz et al. 1999). Studies have also suggested that cocaine dependence can develop more rapidly in women than in men with women being 3–4 times more likely to become cocaine dependent within 24 months of cocaine onset (McCance-Katz et al. 1999, O’Brien and Anthony 2005). In a study of treatment seeking cocaine abusers, women used cocaine by more addictive routes (smoked, intravenous) than did men in this sample (McCance-Katz et al. 1999). Cocaine-dependent women in treatment have been shown to have a lower overall level of social adjustment than men who are more likely to be employed, support themselves financially, and finance their own drug habits (McCance-Katz et al. 1999, Weiss et al. 1997). More women may have a mood disturbance that meets diagnostic criteria for major depressive disorder than men, although men have been shown to more often have a diagnosis of antisocial personality disorder (Magura et al. 1998, Weiss et al. 1997). It has also been reported that women experience increased craving for cocaine in response to cocaine-specific cues (Robbins et al. 1999). These findings suggest that newly abstinent women may experience greater levels of psychological distress and intense craving that may persist for some time following abstinence. The more rapid course of addiction and the slower recovery from depressive symptoms would indicate that the course following cocaine abstinence could be more severe in women. In terms of response to treatment interventions, outcomes in women are improved if their specific needs, for example prenatal and childcare, are addressed (Kissin et al. 2001, Kosten et al. 1993, Weiss et al. 1997). Further, a recent analysis found that men treated with disulfiram for cocaine dependence had better outcomes than women (Nich et al. 2004), emphasizing the likelihood of significant differences in responses to psychosocial and pharmacological treatments for cocaine use disorders by gender differences and the need to adequately include women in substantial numbers in treatment clinical trials.

Cocaine is one of the most frequently abused illicit drugs during pregnancy (SAMHSA 2005). It has been estimated that 0.3% of pregnant women are cocaine users (SAMHSA 2005) The risks of cocaine and other substance abuse during pregnancy are significant not only for women but also for their unborn children who may be at increased risk of vascular injury to the central nervous system (Frank et al. 1999). Abuse of cocaine has been linked to placental abruption, preterm labor, and low birth weight (Buehler 1995, Buehler et al. 1996). Abuse and neglect of children are also common consequences of parental addiction (Luthar et al. 1998, Suchman and Luthar 2000). Some studies have suggested that children exposed to cocaine in utero do not appear to have permanent sequelae attributable to maternal cocaine abuse (Frank et al. 2001, Hurt et al. 1997, Richardson 1998, Richardson et al. 1996, Richardson et al. 1999, Smeriglio and Wilcox 1999). However, Griffith et al. found that cocaine-exposed children had lower verbal reasoning scores than nonexposed children (Griffith et al. 1994) while another study demonstrated that cocaine-exposed boys have lower IQ scores at age 4 when compared with nonexposed counterparts (Bennett et al. 2002). Further, some researchers have shown that cocaine exposure effects head circumference which in turn effects development (Azuma and Chasnoff 1993, Behnke et al. 2002, 2006).

Relationship of Psychiatric Disorders to Cocaine Abuse and Dependence

Earlier epidemiological surveys had failed to identify demographic characteristics, personality traits, or features of early cocaine use that differentiate noncompulsive and heavy use (Schnoll et al. 1985). However, recent studies suggest that a particular personality trait known as novelty or sensation seeking may play an important role in the initiation of cocaine use (Laviola et al. 1999). Additionally, comorbid conditions related to cocaine abuse are abuse of other substances (Birnbaum et al. 2001, Usdan et al. 2001, Withers et al. 1995) and comorbid psychiatric illness (Volkow 2001). Several studies have documented the high rate of comorbid psychiatric disorders in cocaine abusers entering treatment. These disorders include mood disorders (major depressive disorder, bipolar disorders), schizophrenia, posttraumatic stress disorder, attention-deficit/hyperactivity disorder, anxiety disorders, and antisocial personality disorder (Brady et al. 1998, Brown et al. 1998, Cassidy et al. 2001, Clure et al. 1999, Dixon 1999, Eames et al. 1998, Marlowe et al. 1997, Najavits et al. 1997, Schmitz et al. 2000, Sherwood Brown et al. 2001, Skinstad and Swain 2001, Thomas et al. 1999, Westermeyer et al. 1997). Mood disorders often temporally follow
the onset of cocaine abuse in patients presenting for treatment, while attention-deficit/hyperactivity disorder and antisocial personality disorder predict the onset of cocaine abuse (Clure et al. 1999, McMahon et al. 1999). However, while high levels of depressive symptoms during treatment were associated with greater craving for cocaine, alcohol, and other substances, only limited evidence exists regarding the influence of depression on treatment course and outcome (Carroll et al. 1995a, Brown et al. 1998, Simpson et al. 1999).

It is important to note that comorbid psychiatric illnesses are common among cocaine users. Furthermore, the diagnosis of a comorbid primary psychiatric disorder can be challenging to make in cocaine abusers because psychiatric symptoms may be the result of cocaine abuse or acute abstinence. When psychiatric disorders co-occur with cocaine use disorders, it is important to provide treatment for both disorders. Cocaine use disorders will not generally resolve with treatment of the psychiatric disorder alone, nor will substance abuse treatment resolve a comorbid psychiatric disorder.

**Course and Natural History**

Cocaine produces a sense of intensified pleasure in most activities and a heightened sense of alertness and well being. Anxiety and social inhibition are decreased. Energy, self-esteem, and self-perception of ability are increased. There is enhancement of emotion and sexual feeling (Bolla et al. 1998, Lesher and Koob 1999). Pleasurable experiences, although heightened, are not distorted and hallucinations are usually absent. The person engaging in low-dose cocaine use often receives positive feedback from others responding to the user’s increased energy and enthusiasm. This, in combination with the euphoria experienced by the user, can be reinforcing, and cocaine use is perceived as free of any adverse consequences. The duration of cocaine’s euphoric effects depends on the route of administration. The faster the drug is absorbed and occupies receptors of the “brain rewarding region,” the more intense the euphoric effects (Koob 1999, Lesher and Koob 1999, Ward et al. 1997a).

Cocaine and alcohol are often consumed together. In addition to the synergistic effects of cocaine and alcohol in humans, an active metabolite, cocaethylene, with cocaine-like pharmacological properties is formed and users of both drugs simultaneously report enhanced euphoria (Andrews 1997, Hart et al. 2000, McCance-Katz et al. 1993, McCance-Katz et al. 1998a).

Cocaine users quickly learn that higher doses are associated with intensified and prolonged euphoria, resulting in increasing use of the drug and progression to cocaine dependence. The abuser is focused on the cocaine-induced euphoria and begins to compulsively pursue this effect. These behaviors become pivotal in the lives of cocaine abusers who continue drug abuse despite the presence of increasing personal and social consequences (Bolla et al. 1998, Ward et al. 1997a).

The psychoactive effects of cocaine are similar to those of amphetamine; the main difference in terms of abuse liability is in cocaine’s much shorter duration of action. Whereas the plasma elimination half-life for cocaine is approximately 90 min, this drug produces pharmacodynamic tachyphylaxis resulting in rapidly diminishing psychoactive effects in the presence of continued cocaine in the plasma. This phenomenon explains the “half-life” of cocaine-induced euphoria, (which is approximately 45 min after intranasal use and 5 min after intravenous and smoking administration) as well as characteristic binge use in which cocaine is repetitively administered over short intervals (Jufer et al. 2000, Mendelson et al. 1999, Moolchan et al. 2000). During binge use, the drug may be administered as frequently as every 10 min, resulting in rapid mood changes. Cocaine binges reportedly can last as long as 7 days, although the average length is 12 hours (Evans et al. 1999, Foltin and Fischman 1997, Foltin and Fischman 1998, Pottieger et al. 1995, Ward et al. 1997b).

Uncontrolled use of cocaine often begins with either increased access and resultant escalating dosages and frequency of administration or a change from intranasal use to a route of administration with more rapid onset of effects (i.e., intravenous or smoked) (Foltin and Fischman 1998, Ward et al. 1997a). These characteristics are integral to the development of high-dose binging with cocaine. Such binges produce extreme euphoria and vivid memories. These memories are later contrasted with current dysphoria to produce intense craving, which perpetuates the binge use pattern (Margolin et al. 1996, Uslaner et al. 1999). Addicts report that during binge use, thoughts are focused exclusively on the cocaine-induced effects. Normal daily needs, including sleep and nourishment, are neglected. Responsibilities to family and employer and social obligations are given up. This continues until the supply of cocaine is exhausted.

Binges are often separated by several days of abstinence; cocaine-dependent individuals average 1 to 3 binges per week. This is in contrast to use patterns for opiate and alcohol dependence which often produce physiological dependence necessitating daily consumption to prevent withdrawal symptoms. This differentiation is crucial to an understanding of the syndrome of cocaine dependence (Evans et al. 1999, Pottieger et al. 1995). Although the prediction of development of cocaine use disorders is not possible on an individual basis, it is clear that those who progress to binge use of the drug will be significantly affected and constitute the treatment-seeking population. The cocaine abuser is likely to be ambivalent about the need for treatment, and the treatment dropout rate is high (ranging from 38 to 73%). Dropout usually occurs early in treatment (during the initial evaluation process) (Chou et al. 1998, Fiocchi and Kingree 2001, Siqueland et al. 1998, Simpson et al. 1997).

Newly abstinent cocaine abusers may experience a triphasic abstinence pattern, although this varies by individual, that includes a period of acute abstinence, sometimes referred to as the “crash,” lasting several hours to several days consisting of dysphoria, fatigue, insomnia or hypersomnia, increased appetite, and either psychomotor agitation or retardation, subsequent to the more intensive “crash” phase. A more chronic withdrawal period sometimes occurs characterized by minor depressive symptoms and cocaine craving lasting 2–10 weeks. This may then be followed by an extinction phase characterized by intermittent drug craving that becomes increasingly manageable with continued abstinence.

Like other drug and alcohol use disorders, cocaine use disorders are chronic relapsing illnesses that present substantial challenges in the treatment process. Cocaine abusers are at high risk for relapse, particularly in the first few months of treatment related to acute craving often in the context
of ongoing psychosocial stressors that result from or have been exacerbated by cocaine abuse. Newly abstinent cocaine abusers often lack adequate coping skills necessary to avoid cocaine use, which take time to acquire in the treatment process. Although the ability to cope with cocaine craving improves with continued abstinence, relapse to cocaine abuse or other drug and alcohol abuse will continue to be a risk for those with a history of a cocaine use disorder who relapse to cocaine abuse. Repeated treatments may be required for those with cocaine use disorders. Treatment modalities include inpatient hospitalization for medical or psychiatric complications of cocaine abuse, partial hospital programs, self-help groups, psychotherapy (usually group or family therapy for patients with primary cocaine use disorders), or some combination of these treatments according to the clinical presentation of the patient (see later in the chapter).

**Etiology and Pathophysiology**

**Genetic Vulnerability to Cocaine Abuse and Dependence**

Heritability or genetic vulnerability may play an important role in the development of cocaine addiction. Epidemiological studies of twins suggest that while both genetic and environmental factors play a role in twin concordance of cocaine use, concordance of abuse and dependence are more influenced by genetic factors (Kendler and Prescott 1998, Kendler et al. 2000). While no single gene has been definitively linked to cocaine use disorders, certain alleles may play a role in the development of cocaine use disorders and/or clinical manifestations of these disorders. Population-based genetic association studies have yielded some interesting preliminary results. For example, an association between cocaine-induced paranoia and an allelic polymorphism in the dopamine transporter protein (DAT) (allele 9) has been described (Gelernter et al. 1994). Another study reported on a haplotype at the dopamine beta-hydroxylase (DBH) locus associated with low plasma DBH activity that appears to be associated with cocaine-associated paranoia, (Cubells et al. 2000). The tryptophan hydroxylase gene, responsible for the majority of serotonin production in neurons has been shown to have no association with cocaine dependence (Dahl et al. 2006). A genome-wide linkage scan conducted in families with at least one subject affected with cocaine dependence suggested a linkage signal for cocaine dependence on chromosome 10 and two suggestive linkages for cocaine dependence for European Americans on chromosome 3. Further, this study showed a suggested linkage on chromosome 9 for cocaine-associated paranoia in the African American sample, while heavy or moderate cocaine use in the European American sample was associated with chromosones 12 and 18, respectively (Gelernter et al. 2005). Such findings together with ongoing candidate gene studies using genetic engineering techniques and genome mapping may contribute to important advances in our understanding of genetic vulnerability to cocaine abuse and dependence (Kuhar et al. 2001).

**Neurobiological Changes Related to Acute Cocaine Use**

Cocaine has effects on multiple neurotransmitters, including release and reuptake blockade of dopamine, serotonin (5-hydroxytryptamine [5-HT]), and norepinephrine (Hemby 1999, Koob 1999). The most widely accepted explanation of cocaine-induced euphoria is that dopamine reuptake inhibition results in increased extracellular dopamine concentrations in the mesolimbic and mesocortical reward pathways in the brain. Numerous studies have provided evidence for the importance of dopamine in the reinforcing properties of cocaine. For example, 6-hydroxydopamine lesions of dopaminergic terminals in the nucleus accumbens produce extinction-like responding and a reduction in cocaine self-administration. Similar lesions in other areas of the brain (frontal cortex and caudate nucleus) do not alter cocaine self-administration (Schenk et al. 1991, Brown and Fibiger 1993, Reavill et al. 1998).

*In vivo* brain microdialysis and neuroimaging studies using functional magnetic resonance imaging (fMRI), PET, and SPECT, have provided additional direct evidence that the limbic region and other dopamine rich structures in the brain are associated with cocaine reward (Gatley and Volkow 1998, London et al. 1999, Hommer 1999). Cocaine-induced euphoria has been associated with activity in many areas of the brain but primarily in the prefrontal cortex as evidenced by reduced cerebral glucose metabolism (London et al. 1996, Bolla et al. 1998, London et al. 1999) and reduced cerebral blood flow (CBF) (Pearlson et al. 1993, Breiter et al. 1997, Gollub et al. 1998). Moreover, SPECT neuroimaging has shown that the euphoric effects of cocaine are associated with blockade of the dopamine transporter (Malison et al. 1995, 1998a, Volkow et al. 1999). Cue-induced craving increases activation in the limbic regions including dorsolateral prefrontal cortex, cerebellum, anterior cingulate, and amygdala (London et al. 1999, Childress et al. 1999, Garavan et al. 2000). These structures have been linked to memory and learning. The amygdala, in particular, is linked to the emotional aspect of memory (Rolls 2000, Cahill 2000, LeDoux 2000). Studies using fMRI technology showed that cocaine-specific cues activated the same limbic regions activated by other pleasurable stimuli (such as sex in cocaine users) but had almost no effect on nonusers (Childress et al. 1999, Garavan et al. 2000, Stein 2001).

Another important phenomenon related to acute cocaine administration is that of “acute tolerance.” A single dose of cocaine has been shown experimentally to reduce the response to a second identical dose given 100 min later as measured by extracellular dopamine levels and motor activity (Bradberry 2000). The finding of “acute tolerance” is consistent with the binge pattern of cocaine use in which abusers consume escalating doses of cocaine in an attempt to recapture the intense euphoria of the initial cocaine dose (Bradberry 2000).

There may also be other neurochemical processes important to both the positive and the negative reinforcing properties of cocaine. Although dopamine reuptake inhibition is important to the reinforcing effects of cocaine, it cannot fully account for these effects. Numerous agents that are dopamine reuptake inhibitors are not abused by humans and are not self-administered by animals. These include benzotropine, nomifensine, and mazindol. Similarly, other agents that are not abused by humans mimic neurochemical actions of cocaine on noradrenergic or serotoninergic systems. Studies have shown that “knockout” mice lacking the genes for either the dopamine or serotonin transporters continue to find cocaine rewarding (Miner et al. 1995, Sora et al. 1998, Uhl et al. 1996). However, when both transporter...
Long-Term Cocaine Use

Neurobiological Changes Related to Long-Term Cocaine Use

A growing body of evidence indicates that chronic cocaine administration can result in sustained neurophysiological changes in brain systems that regulate psychological processes, specifically pleasure and hedonic responsivity (Bolla et al. 1998). This has been postulated to underlie a physiological addiction to cocaine with associated withdrawal phenomena that are manifested clinically as a psychological syndrome (Koob and Nestler 1997). Long-term cocaine administration in animals is associated with an increase in dopamine transporter binding sites, a decrease in intracranial electrical self-stimulation in dopaminergic brain reward areas, such as the nucleus accumbens, and an increase in the voltage required to elicit intracranial electrical self-stimulation (Richter et al. 1995, Weiss et al. 2001b). These findings imply that an alteration in brain reward regions affected by cocaine occurs with chronic use and is also associated with blunted responses to usual reward stimuli such as sex and food. The impairment of brain rewarding systems resulting from cocaine self-administration in rodents has been shown to be reversed with administration of bromocriptine, a dopaminergic agonist (Markou and Koob 1992). Interestingly, withdrawal from chronic self-administration of cocaine was reported to be associated with depletion of extracellular serotonin in the nucleus accumbens (Parsons et al. 1995) and an increase in serotonin transporter binding sites in the brainstem (Mash et al. 2000), resulting in a decrease of serotonin availability in synapses (Jacobsen et al. 2000). Given the role of serotonin in depression and anxiety, the findings are supportive of clinical observations of periods of anhedonia in cocaine abusers following initiation of abstinence (Weiss et al. 2001a). Neurophysiological changes that could help to explain these experimental and clinical observations include findings in animal studies of dopaminergic, alpha-adrenergic, and beta-adrenergic receptor supersensitivity with chronic cocaine administration (Hemby 1999). Dopaminergic autoreceptor supersensitivity results in a net decrease of dopaminergic neurotransmission. Animal studies in which cocaine is continuously administered have confirmed that such changes occur (Clay et al. 1998, Kuhar and Pilotte 1996, Pilotte et al. 1996). Chronic administration of cocaine has also been shown to alter the activity or expression of diverse types of cellular proteins in specific target neurons within the central nervous system. Prominent examples include signaling proteins, G proteins, second-messenger synthetic enzymes, and protein kinases (Carlezon et al. 1998, Hwang et al. 2001, Kelz et al. 1999, Nestler 2001). In addition, recent work has focused on a role for transcription factors and associated alterations in gene expression in mediating part of this long-lasting, drug-induced, molecular and behavioral plasticity (Nestler 1997, 2001).

Diagnosis of Cocaine Use Disorders

The initial evaluation period should include the collection of a complete history of all substance abuse (including alcohol and drug abuse), which is essential to accurate diagnosis and appropriate treatment. The history includes the circumstances under which each drug was used, the psychotropic active effects sought and obtained, the route of administration, age of onset of each drug used, and the frequency and amount of each drug used. Cocaine abusers frequently abuse other drugs and alcohol to enhance euphoria or to alleviate dysphoric effects associated with cocaine abuse (e.g. agitation, paranoia). A thorough history with diagnosis of other substance use disorders is important to treatment planning. Patients may need detoxification from other substances prior to initiation of cocaine abuse treatment. It is also important to monitor clinically for relapses to any substance abuse during treatment for cocaine use disorders because the use of other drugs and alcohol often leads to resumption of cocaine abuse. In addition, a thorough history of current and previous substance abuse is important so that treatment can be individualized and patients can be helped to develop coping skills that will assist them in specific situations that they identify as placing them at high risk for relapse.

A careful psychiatric history with particular attention to onset of psychiatric symptoms in relation to drug use is essential. The determination of a premorbid psychiatric illness is critical to providing appropriate treatment. For persons in whom substance abuse is an attempt to self-medicate an underlying mental illness, the introduction of psychotropic medication in conjunction with ongoing treatment for the substance abuse will improve both the psychiatric disorder as well as the substance use disorder(s). Conversely, the evaluation of temporal onset of psychiatric symptoms may preclude erroneous use of psychotropic medication in cases in which the psychiatric symptoms are in fact cocaine-induced and spare the patient exposure to the potential side effects of these medications.

A complete physical examination is necessary to determine whether medical complications of substance abuse are present. Common medical problems seen in those with cocaine use disorders include poor nutrition, vitamin deficiencies, anemia, human immunodeficiency virus (HIV) infection, and sexually transmitted diseases. In those who self-administer the drug by injection or who abuse other drugs in addition to cocaine by the intravenous route, endocarditis, abscesses, cellulitis, and Hepatitis B and C occur with regularity. The clinical evaluation should include blood studies to determine the presence of abnormalities and urine toxicology screen to determine recent drug use.

**DSM-IV-TR Criteria**

**Substance (Cocaine) Abuse**

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

1. recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, (continues)
Cocaine Use Disorders

Cocaine Abuse
Substance abuse is described by DSM-IV-TR as a maladaptive pattern of substance use demonstrated by recurrent and significant adverse consequences related to repeated use. For example, there may be neglect of obligations to family or employer, repeated use in hazardous situations, legal problems, and recurrent social or interpersonal problems. These problems must recur within the same 12-month period. The intensity and frequency of use are less in cocaine abuse than in cocaine dependence. Episodes of abuse may occur around paydays, days off from work or weekends, holidays or special occasions and may be characterized by brief periods (hours to days) of high-dose binge use followed by longer periods of abstinence or nonproblem use.

Cocaine Dependence
The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000) defines the essential features of substance dependence as a cluster of cognitive, behavioral, and physiological symptoms indicating continued use of the substance despite significant consequences of use. There is a pattern of administration that usually results in tolerance to and compulsive self-administration of the drug and

1. tolerance, as defined by either of the following:
   a. a need for markedly increased amounts of the substance to achieve intoxication or desired effect
   b. markedly diminished effect with continued use of the same amount of the substance
2. withdrawal, as manifested by either of the following:
   a. the characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)
   b. the same (or a closely related) substance taken to relieve or avoid withdrawal symptoms
3. the substance is often taken in larger amounts or over a longer period than was intended
4. there is a persistent desire or unsuccessful efforts to cut down or control substance use
5. a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), using the substance (e.g., chain-smoking), or recovering from its effects
6. important social, occupational, or recreational activities are given up or reduced because of substance use
7. the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Specify if:
With physiological dependence: evidence of tolerance or withdrawal (i.e., either item 1 or 2 is present)
Without physiological dependence: no evidence of tolerance or withdrawal (i.e., neither item 1 nor 2 is present)

may produce a withdrawal syndrome on cessation of drug use. Cocaine dependence can develop quickly after initiation of use because of the potent euphoria produced by the drug. The route of administration is related to the development of cocaine dependence; smoked and intravenous routes are more highly correlated with dependence than the intranasal route of administration.

Cocaine has a short half-life requiring frequent dosing to maintain the “high” (binge use). Persons with cocaine dependence often spend large amounts of money for the drug and may be involved in illegal activities to obtain cocaine. Binges may be separated by several days while the individual recovers or attempts to obtain more money for drug purchase. Illegal activities such as theft and prostitution are often engaged in to obtain cash for cocaine. Obligations such as employment and childcare are often neglected. Tolerance to cocaine effects develops quickly, resulting in larger amounts of drug use with time. This is often associated with mental or physical complications of use including paranoia, aggressive behavior, anxiety and agitation, depression, and weight loss. Withdrawal symptoms, most prominently dysphoric mood, may be seen but are usually short-lived and clear within several days of abstinence.

**Cocaine Intoxication**

The clinical effects of cocaine intoxication are characterized initially by euphoria (referred to as high) and also include agitation, anxiety, irritability or affective lability, grandiosity, impaired judgment, increased psychomotor activity, hypervigilance or paranoia, and sometimes hallucinations (visual, auditory, or tactile) may occur. Physical symptoms that can accompany cocaine intoxication include hypertension, tachycardia, hyperthermia, mydriasis, nausea, vomiting, tremor, diaphoresis, chest pain, arrhythmia, confusion, seizures, dyskinetic movements, dystonia, and, in severe cases, coma. These effects are more frequently seen in high-dose binge users of cocaine. Cardiovascular effects are probably a result of sympathomimetic properties of cocaine (i.e., release of norepinephrine and blockade of norepinephrine reuptake).

**Cocaine Withdrawal**

The principal feature of substance withdrawal is development of a substance-specific maladaptive behavioral change, which may have associated physiological and cognitive components, resulting from the cessation of or reduction in heavy and prolonged substance use. The syndrome is characterized by significant distress or impairment in function. Symptoms must not be better explained by a mental or physical disorder. Cocaine withdrawal develops within a few hours to a few days after stopping or reducing cocaine use that has been heavy and prolonged. The syndrome is characterized by dysphoria and two or more physiological changes including fatigue, vivid and unpleasant dreams, insomnia or
hypersomnia, hyperphagia, and psychomotor agitation or retardation. Anhedonia and craving for cocaine can be part of the withdrawal syndrome. Depression and suicidal ideation are the most serious complications and require individualized assessment and treatment. The syndrome may last up to several days but generally resolves without treatment.

**Other Cocaine-Induced Disorders**

DSM-IV-TR also specifies additional cocaine-induced disorders described in other diagnostic groupings with which they share phenomenology (Table 58–1). These include cocaine intoxication delirium, cocaine-induced psychotic disorder, cocaine-induced mood disorder, cocaine-induced anxiety disorder, cocaine-induced sleep disorder, and cocaine-induced sexual dysfunction. These disorders are diagnosed instead of intoxication or withdrawal only if symptoms are in excess of those usually associated with cocaine intoxication or cocaine withdrawal and warrant independent clinical attention. In addition, the psychiatrist should pay careful attention to the temporal relationship of the psychiatric symptoms and cocaine abuse. Symptoms that are severe enough to warrant consideration of one of these diagnoses should also dissipate with continued abstinence from cocaine. Symptoms that worsen after cessation of cocaine use in a period of 1–4 weeks should be reevaluated and other Axis I or Axis III disorders considered with modification of the treatment plan as clinically indicated.

**Medical Complications of Cocaine Abuse**

Cardiac toxicity is one of the leading causes of morbidity and mortality associated with cocaine use. The risk of myocardial infarct is well established in cocaine use (Pitts et al. 1997, 1998) and is not related to dose, route, or frequency of administration (Lange and Hillis 2001). The risk of acute myocardial infarction is increased 24-fold in the first hour immediately following cocaine use in those who are otherwise at relatively low risk for such events (Mittleman et al. 1999). Another potential source of medical comorbidity is the concomitant use of cocaine and alcohol which leads to the formation of cocaethylene, a compound with properties similar to those of cocaine (Hart et al. 2000, McCance et al. 1995). Cocaethylene has been associated with a 40-fold increase in risk for acute cardiac events and 25-fold increase in sudden death (Keegan 1991) and places users at heightened risk for toxicity than with either drug alone (McCance-Katz et al. 1998). Detection of recent cocaine use by urine toxicology screen has been observed in 25% of those reporting to urban emergency departments and 7% of those evaluated at suburban hospitals and found to have evidence of myocardial infarct (Hollander et al. 1995). About half of the patients with cocaine-related myocardial infarction have no evidence of atherosclerotic coronary artery disease (Hollander et al. 1997a, b). Identifying and diagnosing cocaine-related myocardial infarction can be difficult. The hallmarks of myocardial infarct are a constellation of physical symptoms including chest pain, electrocardiogram (ECG) abnormalities, and elevated creatine kinase. Cocaine abusers with chest pain may have ECG abnormalities that are not specific for myocardial infarct (Hamad and Khan 2000, Hollander et al. 1994, 1998a, Weber et al. 2000). Cocaine abusers also are often found to have nonspecific elevations in creatine kinase without myocardial infarction (Hollander et al. 1998b). Therefore, the diagnosis of cocaine-related myocardial infarction is often based on the physician’s clinical judgment. Evaluation of serum troponin I, a cardiac marker that is not affected by recent cocaine use, can be helpful in determination of whether a myocardial infarct has occurred (Hollander et al. 1998b, Lange and Hillis 2001).

The pathophysiology of cocaine-related myocardial infarction is probably multifactorial. The sympathomimetic effects of cocaine increase myocardial oxygen demand by increasing heart rate, systemic blood pressure, and left ventricular contractility while reducing oxygen supply through its coronary artery vasoconstriction effects (Baumann et al. 2000). Cocaine-induced coronary artery vasoconstriction is thought to be mediated by an alpha-adrenergic mechanism since it can be reversed with phentolamine, an alpha-adrenergic antagonist, and is exacerbated by propranolol, a beta-adrenergic antagonist (Hollander 2001, Lange and Hillis 2001). The vasoconstrictive effects of cocaine are more prominent in segments of the coronary artery with preexisting atherosclerotic lesions. Consequently, cocaine users with atherosclerotic coronary artery disease are at an increased risk for ischemic events (Lange and Hillis 2001). Additionally, cocaine may induce thrombus formation, enhance platelet aggregation, and decrease fibrinolysis by increasing the concentration of plasminogen-activator inhibitor (Kugelmass et al. 1993, Lee et al. 1995, Molliterno et al. 1994, Rezkalla et al. 1993, Rinder et al. 1994, Siegel et al. 1999). Postmortem as well as in vitro studies have suggested that cocaine may contribute to the pathogenesis of premature atherosclerotic formation by damaging the endothelial cell barrier, increasing its permeability to low-density lipoprotein and enhancing the expression of endothelial adhesion molecules and migration of leukocytes (Gan et al. 1999, Kolodgie et al. 1995, 1999, Lange and Hillis 2001). The American Heart Association treatment guidelines for emergency cardiovascular care indicate that nitroglycerin and benzodiazepines are first line agents and phentolamine
is a second line agent for patients with cocaine-related acute coronary syndrome. Propranolol is contraindicated as it exacerbates cocaine-induced vasoconstriction of coronary arteries. Fibrinolytics should be used with caution if at all, particularly in the presence of severe hypertension. Intracoronary fibrinolytic administration is preferred to peripheral administration. The use of labetolol is controversial because it blocks the peripheral signs of drug-induced sympathetic excess without affecting central nervous system effects such as seizures. Esmolol and metoprolol may induce hypotension (American Heart Association 2005).

Cocaine use is associated with a wide range of cardiac arrhythmias including sinus tachycardia, sinus bradycardia, supraventricular and ventricular tachycardia, ventricular premature contractions, ventricular tachycardia and fibrillation, torsades de pointes and asystole (Castro and Nacht 2000, Gamouras et al. 2000, Kerns et al. 1997, Perera et al. 1997, Singh et al. 2001). While the precise arrhythmogenic mechanism of cocaine is unclear, limited evidence suggests it may be due to cocaine’s sodium-channel-blocking property similar to class I antiarrhythmic drugs that prolong the QRS and QT intervals on ECG (Brady and Chan 1999, Kerns et al. 1997). Life-threatening arrhythmia caused by cocaine in the absence of myocardial ischemia is rare. In many instances, cardiac arrhythmias have occurred in the context of profound hemodynamic or metabolic disturbances (Wang 1999). Patients with cocaine-induced ventricular arrhythmias and heart block should receive standard therapy including the treatment of ischemia if present, the correction of metabolic disturbances, and the administration of appropriate antiarrhythmic agents (Lange and Hillis 2001). Class IA antiarrhythmic drugs, such as quinidine, procardiamide, and diisopyramide, should be avoided since they may exacerbate prolongation of the QRS and QT intervals and slow the metabolism of cocaine.

Several cases of cardiomyopathy and left ventricular hypertrophy attributed to cocaine use have been reported (Fineschi et al. 1997, Missouri et al. 2001). The condition is often associated with chronic cocaine use and cocaine-related myocardial ischemia and infarction. While the exact underlying mechanisms of cocaine-induced cardiomyopathy and hypertrophy are still unclear, the process may involve repetitive sympathetic stimulation by cocaine with altered myocardial collagen and myosin composition in endothelial cells (Besse et al. 1997, He et al. 2000, 2001, Huang et al. 1997, Mao et al. 1997, Woolf et al. 1997, Xiao et al. 2000). A few cases of aortic dissection have also been reported in association with cocaine abuse (Baumgartner and Omari 1997, Madu et al. 1999, Perron and Gibbs 1997). This adverse event might be associated with sudden increase in blood pressure following cocaine use.

Intranasal abuse of cocaine has been associated with a number of medical complications including chronic sinusitis, septal perforation, subperiosteal abscess, pneumomediatinum, pneumothorax, and pulmonary edema (Gende et al. 1998). The presence of pulmonary edema in a young, otherwise healthy patient, without predisposing risk factors, should alert the physician to the possibility of cocaine abuse (Albertson et al. 1995, Bird and Markey 1997, Boghdadi and Henning 1997, Cuenca Carvajal et al. 1998).

Cerebrovascular accidents related to cocaine use have been well documented in the medical literature (Alves and Gomes 2000, Blanco et al. 1999, Daraset al. 2001, Kaufman et al. 1998, Kaufman et al. 2001, Neiman et al. 2000, Nwosu et al. 2001, Petitti et al. 1998, Qureshi et al. 2001, Tolat et al. 2000). Cerebral infarct, subarachnoid hemorrhage, intraparenchymal hemorrhage, and intraventricular hemorrhage have been observed as acute complications of cocaine use. The physiological etiology of these events appears to be related to adrenergic stimulation resulting in a sudden surge in blood pressure. Abrupt increases in blood pressure in otherwise normotensive individuals may precipitate spontaneous bleeding (Neiman et al. 2000, Strickland et al. 1998). Additional risk would be encountered by a cocaine user with an arteriovenous malformation or cerebral artery aneurysm.

Seizures were one of the earliest known complications of cocaine abuse (Chiarotti and Fucci 1999, Koppel et al. 1996, O’Connell and Heffron 2000, Steele et al. 2000, Winbery et al. 1998). Cocaine produces hyperpyrexia which in combination with its effects on neurotransmitters may contribute to the development of seizures (Boghdadi and Henning 1997, Winbery et al. 1998). Seizures may occur as a primary effect of cocaine owing to its ability to lower the seizure threshold or may be secondary to other central nervous system or cardiac events precipitated by cocaine use (Koppel et al. 1996). One study retrospectively analyzed 474 cases of cocaine-related seizures. Of these, 403 had no history of seizures. It was found that the majority of seizures were single, generalized, and induced by intravenous or “crack” cocaine abuse not associated with any lasting neurological deficits. Seizures that were focal, multiple, or occurred with nasal cocaine use were more frequently associated with an acute intracerebral complication or concurrent use of other drugs (Chiarotti and Fucci 1999, Koppel et al. 1996, Pascual-Leone et al. 1990). While anticonvulsants have not been helpful in preventing cocaine-related seizures, intravenous diazepam has been effective in acute management (Koppel et al. 1996). These findings imply that there is no clinical benefit to chronic anticonvulsant therapy in those who experience a cocaine-related seizure, rather substance abuse treatment for the cocaine use disorder is indicated.

Recently, acute renal failure as a result of rhabdomyolysis has been recognized as an important complication of cocaine abuse (Horowitz et al. 1997, Lempley et al. 1996, Ruttenber et al. 1999, Richards 2000, van der Woude 2000). Pregnancy may increase the risk of rhabdomyolysis and renal failure (Lempley et al. 1996). Renal failure may progress rapidly in the context of cocaine-induced rhabdomyolysis and dialysis may be necessary for some patients. The mechanism for this complication is unclear. Some possibilities include increased muscle activity, muscle compression, hyperthermia, and vasospasm with muscle ischemia (Richards 2000, Ruttenber et al. 1999, van der Woude 2000).

The major medical complications of cocaine abuse are summarized in Table 58–2.

Treatment of Cocaine Use Disorders
Cocaine continues to be the most frequently mentioned illicit drug associated with medical adverse events, comprising 19% of all drug-related emergency department visits in 2004 with 46% of those with medical adverse events related to cocaine use seeking detoxification (DAWN 2004). Treatments for cocaine use disorders continue to evolve and have been shown to be effective. In a large outcome study,

Cocaine use disorders: Clinical course

Cocaine use disorders: Clinical course

A comparison of short-term inpatient treatment programs, outpatient drug-free programs, and long-term residential programs specifically for those with cocaine use disorders was undertaken. Of those who received any treatment, 24% relapsed to weekly cocaine use, a large decrease over the 73% relapse rate in the year prior to treatment. Some required an additional treatment program (18%) in the year following treatment, which is not an uncommon scenario for this chronic, relapsing disorder. Those with high levels of psychosocial, medical, or psychiatric problems at intake or less than 90 days of treatment had higher cocaine use in the follow-up period. Treatment periods of 90 days or more were associated with better substance abuse outcomes (Crits-Christoph et al. 1999). In this section, the treatment process for cocaine abuse and dependence, including assessment and management of common problems, specific psychotherapies for cocaine use disorders, and pharmacotherapy will be reviewed.

Assessment and Treatment Overview

The two primary goals of cocaine treatment are: (1) the initiation of abstinence through disruption of binge cycles and (2) the prevention of relapse. Treatment planning to achieve these goals must be considered in the context of the individual clinical presentation of the patient. Initial assessment to determine immediate needs is necessary to determine the most appropriate level of care (inpatient or outpatient treatment) as well as other psychiatric and medical considerations important to the development of the treatment plan.

The majority of those with cocaine use disorders are most appropriately treated in an outpatient setting. Outpatient treatment may vary by provider but generally includes multiple weekly contacts for the initial months of treatment because less frequent contact is not effective in the initiation or maintenance of abstinence (Coviello et al. 2001, Gottheil et al. 1998, Katz et al. 2001, Weinstein et al. 1997). These sessions consist of some combination of individual drug counseling, peer support groups, family or couples therapy, urine toxicology monitoring, education sessions, psychotherapy, and psychiatric treatment that may include pharmacotherapy for cocaine addiction and/or comorbid psychiatric disorders. Inpatient treatment is reserved for those who have been refractory to outpatient treatment, whose compulsive use of cocaine represents an imminent danger (e.g., suicidality associated with cocaine toxicity or acute abstinence), who have other comorbid psychiatric or medical disorders complicating their treatment, or who are dependent on more than one substance and require monitored detoxification.

Cocaine Use Disorders: Clinical Course

Cocaine use is characterized by binge use that can occur over extended periods of time and is limited only by the supply of drug or money to purchase the drug. Cocaine toxicity may occur with repeated use of the drug over the course of a binge. Symptoms can include hypervigilance, psychomotor agitation, hyperawareness, and psychosis. While these symptoms generally resolve within 24 hours of cessation of cocaine use, prolonged symptoms may be indicative of an underlying bipolar disorder or psychotic disorder that will need further assessment (Carroll et al. 1994a). Another facet of cocaine toxicity that may be manifested as psychiatric symptoms is that of a syndrome of hyperthermia and agitation resembling neuroleptic malignant syndrome (Daras et al. 1995, Kosten and Kleber 1988, Nolla-Salas et al. 1996, Ross 1998, Wetli et al. 1996). An additional serious complication of cocaine intoxication is that of stimulant delirium characterized by confusion, disorientation, and agitation. This should be treated as a medical emergency since such symptoms may be indicative of cocaine overdose. The medical complications of cocaine abuse have been reviewed (above) and presentation of delirium in a cocaine abuser should prompt a thorough medical evaluation and treatment of any toxic side effects.

Cocaine abstinence symptoms may occur with the cessation of binge use (Foltin and Fischman 1998, Margolin et al. 1996, Milby et al. 2000). The abstinence syndrome is characterized by extreme exhaustion after a binge. Initial depression, agitation, and anxiety are a common experience, followed by craving for sleep. Prolonged hypersomnia and hyperphagia are usually followed by a return to normal mood, although some dysphoria may remain (Rosenblum et al. 1999, Uslaner et al. 1999, Westermeyer et al. 1997).
Cocaine abusers may present to urgent care settings in the context of cocaine toxicity or severe psychiatric symptoms associated with acute abstinence including anxiety, depression, or psychosis. Symptoms may be severe enough to require emergent use of benzodiazepines or antipsychotics. Lorazepam is a good choice for treatment of anxiety, agitation, or psychosis because it can be administered orally and it is also well absorbed by the intramuscular route. The use of benzodiazepines in the severely agitated patient may decrease the need to employ the use of restraints. Antipsychotics should be used sparingly because, like cocaine, these drugs may lower the seizure threshold. In considering the choice of an antipsychotic, low-potency antipsychotics may be more likely than high-potency neuroleptics to lower seizure threshold and therefore should be avoided. Psychiatric management must also include clinical observation because suicidal ideation is not uncommon. Symptoms resembling those of a major depressive episode occur frequently in newly abstinent cocaine abusers. The occurrence of major depressive disorder must be excluded by observation, ideally over several weeks following the initiation of abstinence.

Individuals with cocaine use disorders may experience a withdrawal syndrome upon cessation of binge cocaine abuse that can last for up to 10 weeks. Cocaine withdrawal is marked by decreased energy, lack of interest, and anhedonia. These symptoms fluctuate and are usually not severe enough to meet diagnostic criteria for a major depressive episode. However, this subjective state experienced by the cocaine abuser is contrasted with vivid memories of cocaine-induced euphoria and constitutes a strong inducement to resume cocaine use (i.e., craving). It is during this time that relapse is most likely. Withdrawal symptoms generally diminish over several weeks if abstinence is maintained.

The withdrawal phase is followed by what has been termed “extinction,” an indefinite period during which evoked craving can occur, placing the individual at increased risk for relapse. Craving is evoked by memories of cocaine use, moods, people, locations, or objects associated with cocaine use (money, white powder, pipes, mirrors, syringes) that act as cues to conditioned associations with drug use and drug-induced euphoria (Childress et al. 1993, Ciccioppo et al. 2001, Robbins et al. 1997). Animal models have shown that sensitivity to drug-associated environmental cues and craving lasting 60 days following discontinuation of cocaine administration (Weiss et al. 2000, 2001a, 2001b). Such findings underline the individual’s vulnerability to cocaine relapse well beyond the acute withdrawal phase (Robbins et al. 1999). The documentation of the chronic course of cocaine use disorders has influenced the development of treatment modalities. For example, outpatient treatment is generally recommended to occur over at least three months in an intensive outpatient setting. Those with histories of more severe use problems or frequent relapses may require treatment for longer periods. Pharmacotherapy development has targeted acute abstinence symptoms in which medications would be administered for days and/or weeks and abstinence maintenance in which medication therapy might extend for the duration of the substance abuse treatment. Ongoing supportive groups may be recommended for an indefinite period to assist the cocaine-addicted person in establishing new relationships with peers that will provide support for ongoing sobriety because the experience of drug craving and risk for relapse when the individual is confronted with drug-associated cues can continue for years.

**Overview of Treatment for Cocaine Use Disorders**

Substance abuse treatment for cocaine use disorders has been influenced by the known disease course. One of the greatest challenges in the early stages of cocaine treatment is to prevent drop out. It has been estimated that up to 80% of patients drop out of treatment programs (Higgins et al. 1994). Frequent clinical contacts especially in the early weeks of treatment can help to establish a therapeutic alliance that will assist in engaging the patient in the treatment process. Many programs offer 3–6 days per week of substance abuse treatment sessions within outpatient partial hospital programs or intensive outpatient chemical dependency programs. Assessments by the program physician and counseling staff can identify other areas requiring specific interventions (comorbid medical or psychiatric disorders) and can expedite the initiation of appropriate pharmacotherapies. These interventions will help to improve treatment retention. Often patients must be helped to realize that their drug use is having a significant and adverse impact on their lives. Many patients come to treatment because of family, legal, or social pressures. They may be ambivalent about the need for treatment and require education about their addiction and assistance in reviewing the consequences of cocaine use in their lives. This inventory should occur in the initial visits to the substance abuse treatment program.

Initial treatment should include the encouragement of abstinence from all drug and alcohol use. Patients who abuse alcohol and marijuana often do not perceive these drugs as problems. Education regarding the use of such drugs as conditioned stimuli to the use of cocaine should be emphasized. The “disease model” of chemical dependency may be used to assist in the initiation of abstinence. Emphasis is placed on the patient recognizing chemical dependency as a disease needing treatment to control symptoms, but one for which there is no cure. Comprehensive drug education should also be provided in the initial treatment phase. Frequent contact with a drug counselor is an important part of treatment. Individual, group, and (where clinically indicated) family or marital therapy should be available. Attendance at 12-step or other mutual-help groups is often a useful adjunct to treatment and can be particularly helpful during the early stages of treatment when support for sobriety is essential.

The early recovery phase of treatment varies in duration from 3–12 months and is characterized by multiple weekly contacts and participation in therapeutic modalities with the goal of initiation and maintenance of abstinence. The focus during early recovery should be on relapse prevention and development of new and more adaptive coping skills, healthy relationships, and lifestyle changes that will facilitate abstinence.

During early recovery patients may feel pleased about their progress in treatment, become overly confident about their ability to control use, and test themselves by deliberately encountering what they know to be a high-risk situation for their drug use. Experimentation with cocaine to prove that drug use can be controlled often results in relapse and is associated with guilt. Patients should be informed about the potential for relapse from the start of the treatment process.
Relapse should be reviewed with the patient in a supportive way with an emphasis on helping the patient to gain an understanding of the events leading to relapse. Relapse should, however, also trigger a review of the treatment plan and consideration of the need for additional interventions or whether a higher level of care is needed to assist the patient in the recovery process.

Success with initiating and maintaining abstinence over several months is followed by a reduced frequency of contact (e.g., a decrease to weekly group or individual therapy sessions). The focus should be on maintaining a commitment to abstinence, addressing renewed denial, and continued improvement of interpersonal skills. Participation in mutual-help groups should continue to be encouraged. Mutual-help groups (e.g., Cocaine Anonymous) based on 12-step principles encourage patients to continue to view themselves as addicts in recovery—a cognitive structuring that many recovering drug abusers find helpful in maintaining sobriety.

**Psychotherapies for Cocaine Use Disorders**

A variety of psychotherapeutic strategies for the treatment of cocaine use disorders have been described (Barber et al. 1997, Barber et al. 2001, Carroll et al. 1994a, 1995b, Crits-Christoph et al. 1998, 1999, Crits-Christoph and Siqueland 1996, Higgins et al. 1993) (Table 58–3). In contrast to opiate addiction, for which psychotherapies alone are insufficient (Woody et al. 1995; Woody and Munoz 2000), there appear to be at least some subpopulations of cocaine abusers for whom psychotherapy alone may be adequate (Crits-Christoph et al. 1997, 1998, 1999). Behavioral therapies, in particular cognitive–behavioral therapy (Carroll 1998) and contingency management approaches have been demonstrated to be effective treatments for some cocaine-dependent patients (Elk et al. 1998, Higgins et al. 1991, Jones et al. 2001, Milby et al. 2000).

The lack of a medically dangerous withdrawal syndrome from cocaine suggests that some cocaine abusers may respond to psychotherapy alone in an outpatient treatment setting, compared with opiate- or alcohol-dependent persons for whom hospitalization may be required for detoxification. Another important reason for the development of psychotherapies for the treatment of cocaine use disorders is that no medication is currently approved for the treatment of these disorders. Psychotherapies are also important platforms on which any pharmacological treatment may be supported. Furthermore, individuals not eligible for pharmacological treatment or who do not respond to pharmacological treatment require treatment alternatives such as psychotherapeutic interventions. The following sections discuss psychotherapies that have been used effectively for cocaine use disorders and those currently under investigation.

**Interpersonal Therapy**

Interpersonal or psychodynamically oriented treatment approaches such as interpersonal psychotherapy (IPT) are based on the concept that many psychiatric disorders, including cocaine dependence, are integrally related to disorders in interpersonal functioning that may be associated with the genesis or perpetuation of the disorder. IPT, as adapted for cocaine use disorders treatment, includes four characteristics: (1) adherence to a medical model of psychiatric disorders, which views these illnesses as chronic relapsing disorders, (2) focus on patients’ difficulties in current interpersonal functioning, (3) brevity and consistency of focus, and (4) use of an exploratory stance by the therapist in examining the difficulties being experienced currently by the patient and which may be related to the abuse of cocaine (Carroll and Rounsaville 1993).

**Supportive–Expressive Therapy**

Supportive–expressive therapy is a time-limited, focused psychotherapy. The therapy has two main components: supportive techniques to help patients feel comfortable in discussing their personal experiences related to drug abuse and expressive techniques to help patients identify and work through difficulties in interpersonal relationships. Special attention is paid to the role of drugs in relation to problem feelings and behaviors, and how problems may be solved without recourse to drugs (NIDA 1999b). The efficacy of individual supportive–expressive psychotherapy has been studied with cocaine-abusing, opiate-dependent patients in methadone maintenance treatment who had comorbid psychiatric diagnoses (Woody et al. 1995). It was found that supportive–expressive psychotherapy, when added to drug counseling, improved substance abuse treatment outcomes. Those receiving supportive–expressive therapy had fewer cocaine-positive urine toxicologies and required lower doses of methadone.

**Cognitive–Behavioral Therapy**

Cognitive–behavioral therapy (CBT) is a short-term, focused approach to help cocaine users become abstinent from cocaine and other substances. The underlying assumption is that learning processes play an important role in the development and continuation of maladaptive behaviors such as cocaine abuse. CBT techniques can be used to help cocaine abusers identify and correct behaviors associated with cocaine use (Carroll 1998). Relapse prevention therapy (RPT) is based on cognitive–behavioral principles and attempts to address the serious problem of relapse in substance use disorders through the development of self-control strategies (Carroll et al. 1994a, 1994b). RPT may be especially well-suited as a psychotherapeutic intervention for cocaine abusers because it encompasses several distinctive features important to treating this population. Relapse prevention is oriented toward symptom control. Although the name implies focus on the prevention of relapse, in fact this method employs several strategies intended to facilitate abstinence as well. Specific techniques in cocaine addiction treatment include exploring the positive and negative consequences of continued use, self-monitoring to recognize drug cravings early on and to identify high-risk situations for...
use, and developing strategies for coping with and avoiding high-risk situations and the desire to use. Research indicates that the skills individuals learn through relapse prevention therapy remain after the completion of treatment. In two long-term outcome studies, most people receiving this cognitive-behavioral approach maintained the gains they made in treatment throughout the year following treatment and a proportion of study participants continued to make gains following the termination of the 12-week CBT treatment period (Carroll et al. 1994a, 2000).

Relapse prevention techniques are easily integrated into other treatment modalities. These techniques have been employed in the context of pharmacotherapy, group therapy, brief psychoeducational groups for individuals entering drug-free treatment programs, and intervention for persons at risk for HIV infection (NIDA 1999). RPT is effective given either in a group format or individually (Schmitz et al. 1997). Other studies have shown that CBT/RPT is an effective platform on which to base cocaine pharmacotherapy. In a double-blind, placebo-controlled, clinical trial examining the joint action of naltrexone (NTX) in combination with RPT, patients receiving the combination treatment had less cocaine use over time than those receiving pharmacotherapy or RPT alone (Schmitz et al. 2001b). In a study of the effectiveness of disulfiram alone, CBT or 12-Step Facilitation therapies alone, or disulfiram in combination with either psychotherapy, those assigned to medication plus a psychotherapy had better outcomes in terms of reduced cocaine use and longer periods of abstinence than did those receiving either medication or psychotherapy alone (Carroll et al. 1998).

Voucher-Based/Incentive Treatment
Developed from the theory of alternative reinforcement, the voucher-based treatment approach is another example of behavioral therapy. A model that has been effective for the treatment of cocaine use disorders is that of community reinforcement plus vouchers. Using this model delivered over a 24-week outpatient period, two specific treatment goals are addressed. One goal is the achievement of cocaine abstinence for a period long enough to help patients learn new skills that will help sustain abstinence and the second is the reduction of alcohol consumption in those who consume cocaine and alcohol together. In 1–2 individual counseling sessions weekly, patients focus on improving family relations, learning skills to minimize drug abuse, receiving vocational counseling, and developing new sober social contacts and new recreational activities. Those who abuse alcohol also receive treatment with disulfiram (Antabuse). Urine samples for toxicology screen are submitted 2 to 3 times weekly and vouchers are received for cocaine-free urines. Vouchers can be exchanged for retail goods that would support a drug-free lifestyle (e.g., gift certificates to local stores). This approach has been shown to facilitate patient engagement in treatment and support abstinence both in urban and rural settings in which it has been used (Bickel et al. 1995, Higgins et al. 1994, Silverman et al. 1996).

Motivational Interviewing
Motivational interviewing (MI) was first described by Miller (1983) and further detailed by Miller and Rollnick (1991). The focus of this method is to encourage behavior change by helping patients explore and resolve their uncertainties about which course to follow with regard to their substance use problem. Motivational interviewing is more of a goal-directed therapy when compared to traditional counseling, where the central purpose of MI is to examine and resolve ambivalence and the counselor is intentionally directive in pursuing this goal. A MI pilot study among drug users found that MI significantly increased retention rates six months after commencement of the treatment program (Secades-Villa et al. 2004). Additionally, a meta-analysis by Rubak et al. (2005) provides evidence that MI outperforms traditional advice giving in the treatment of a broad range of behavioral problems and diseases.

Motivational Enhancement Therapy (MET) and brief motivational intervention are adaptations of MI. Brief motivational intervention is the practice of using a single MI session in primary care settings with nonhelp-seeking substance abusing individuals while MET is typically limited to two to four sessions and serves as a prelude to other treatment approaches. These interventions have been used successfully among alcoholics (Burke et al. 2003, Gentilello et al. 1999) and may be a promising adjunct therapy in other drug abuse treatment settings. However, one randomized study in 342 adolescent and young adult ecstasy and cocaine users found that brief motivational intervention was no more effective at inducing behavior change than the provision of information alone (Marsden et al. 2006). Another pilot study in methadone-maintained cocaine users also found no significant treatment benefit from brief motivational intervention, but did observe a modest impact on one crack cocaine measure, therefore supporting the undertaking of a larger trial (Mitcheson et al. 2007). Additional studies among cocaine users have shown that MET (Rohsenow et al. 2004) and brief motivational intervention (Stotts et al. 2001) were beneficial for patients with lower initial motivation. Peer-delivered (nonprofessional, race-matched, recovering cocaine users) MI may further enhance results as one study revealed cocaine levels in hair were reduced by 29% for those in the brief motivational intervention group compared to 4% in the control group at six months (Bernstein et al. 2005). Current literature suggests that MI is less effective than other psychotherapies for cocaine use disorders. MI may be useful in selected patients, but predictors of its success have yet to be identified.

Individual and Group Drug Counseling
Psychotherapeutic approaches are often delivered in the context of multimodal treatment programs and nearly all substance abuse clinicians emphasize the importance of mutual-help groups such as Cocaine Anonymous. The efficacy of psychotherapy for drug abuse was initially established in several studies conducted in opiate-dependent patients receiving methadone maintenance treatment (Kleinman et al. 1990, Rounsaville et al. 1983, Woody et al. 1995, Woody and Munoz 2000). In one study cocaine and heroin using volunteers in three methadone community programs were randomly assigned to 24 weeks of drug counseling alone (control) or drug counseling plus supportive-expressive psychotherapy (treatment). While the treatment and control groups had similar rates of opiate-positive urine samples throughout the study, the treatment group had fewer cocaine-positive urine samples and required lower doses of methadone. Unlike the control group, the gains
associated with the treatment group persisted and in some cases strengthened for at least six months after the end of therapy (Woody et al. 1995). This study shows the effectiveness of combining two therapies, drug counseling plus supportive-expressive therapy, each individually shown to be effective for treatment of cocaine dependence. Many treatment programs combine elements of effective psychotherapies for cocaine dependence into an individualized program for patients. The Woody et al. (1995) provides evidence that such an approach can be effective.

Specific aspects of individual and group drug counseling focus directly on reducing or stopping the use of drugs. It also addresses related areas of impaired social and occupational function as well as the content and structure of the patient’s individualized recovery program. Through its emphasis on short-term behavioral goals, drug counseling helps the patient develop coping strategies and tools for abstaining from drug use and then maintaining abstinence (McLellan et al. 1993).

This premise of increased efficacy of psychotherapy in drug abuse treatment was examined in a multicenter clinical trial, the Drug Abuse Collaborative Cocaine Treatment Study (CCTS), which compared the efficacy of four common psychosocial treatments for cocaine-dependent patients. Participants (N = 487) were randomly assigned to one of the four manual-guided treatments: individual drug counseling + group drug counseling, cognitive–behavioral therapy + group drug counseling, supportive–expressive therapy + group drug counseling, or group drug counseling alone. In this study, those receiving individual drug counseling + group drug counseling showed the greatest improvement in substance use outcomes (Crits-Christoph et al. 1999). This study shows that comprehensive drug counseling treatments that provide both individual and group counseling can be effective for the treatment of cocaine use disorders.

### Systematic Cue Exposure and Coping Skills

One factor that may be an important precipitant to relapse to drug use is that of conditioned responses produced by repeated drug administration in the presence of specific stimuli. First described by Pavlov in 1927, this phenomenon has been reported for cocaine and other psychoactive drugs in animals and humans (Ehrman et al. 1992, O’Brien et al. 1993, Robbins et al. 1997, 1999). Neuroimaging studies have linked cue-induced craving to the limbic region involved in memory, learning, and pleasurable activities such as sex (Childress et al. 1999, Garavan et al. 2000). Research has shown that cocaine abusers exhibit increased limbic activation when watching videos containing cocaine-related scenes. Control subjects with no history of cocaine use show no limbic activation in response to these cues (Childress et al. 1999). Furthermore, while sexually explicit scenes activate the same brain structures in cocaine users and nonusers, the level of activation is less for the cocaine users (Garavan et al. 2000).

Cocaine abusers often report intense craving, arousal, and palpitations when they encounter objects, persons, or situations that remind them of cocaine use. Such cues often result in relapse. Systematic cue exposure and extinction has been studied as a treatment for cocaine addiction (Ehrman et al. 1992, Monti et al. 1997, Rohsenow et al. 2004). To reduce cue-triggered relapse, a treatment technique has been developed that links cue exposure in a clinical setting and teaches cocaine users to control drug use by recognizing these cues (also called triggers) and their responses. Cue exposure is combined with the teaching of coping skills to address high-risk situations. Patients develop skills for how to avoid or modify the trigger situation when possible. For unavoidable triggers, patients are helped to establish a repertoire of cognitive and behavioral skills to disrupt the behavioral chain leading to cocaine abuse. A controlled trial showed that patients in cue-exposure therapy who relapsed had significantly fewer cocaine-using days than did a control group (Monti et al. 1997).

### Physician–Patient Relationship Considerations

The treatment of cocaine use disorders should be undertaken in the context of a thorough understanding of the disease (Table 58–4). The physician should develop individual treatment plans for patients based on the presenting complaints and symptoms related to cocaine abuse and any abstinence syndrome. Treatment plans include assessment for psychiatric and medical illnesses, pharmacological interventions, psychotherapy and other psychosocial interventions. A working knowledge of the course of cocaine use disorders is helpful in educating patients with the goal of gaining insight as to what kinds of symptoms may occur and the temporal relationship of such symptoms (e.g., craving) to cocaine abstinence. Patients with an understanding of what to expect over the course of treatment may be better prepared.

Pharmacotherapies for Cocaine Use

(Higgins et al. 1993, Higgins and Budney 1993), administering disulfiram in the treatment of cocaine dependence programs with good effect. While specifically developed for the medical use of the medication to the treatment process as part of the pharmacotherapy to the treatment process as part of the treatment plan. This has been used in cocaine treatment programs with good effect. While specifically developed for the use of disulfiram in the treatment of cocaine dependence (Higgins et al. 1993, Higgins and Budney 1993), administration of the medication in the clinic can be adapted to other pharmacotherapies for cocaine use disorders as well.

Pharmacotherapies for Cocaine Use Disorders

The development of pharmacological treatments for cocaine abuse has been based on the premise that an altered neurochemical substrate underlies the chronic, high-intensity (binge) use and acute abstinence/withdrawal that follows binge use. This neuroadaptation model has also served as the hypothetical underpinnings for a number of studies that have evaluated the clinical utility of psychotropic agents that, according to their pharmacological profiles, might possess anticraving properties, block euphoria, or decrease cocaine abstinence symptoms. The following section briefly reviews various pharmacotherapies that have been used for the treatment of cocaine abuse. To date, no medication has emerged as a pharmacotherapy approved by the FDA for the treatment of cocaine dependence.

Dopaminergic Agents

Dopaminergic agents have been evaluated to ameliorate early withdrawal symptoms associated with cocaine abstinence. The theoretical basis of this treatment is that habituation use of cocaine results in central dopamine depletion and dopamine receptor supersensitivity. This altered state of dopamine receptor function (or hypofunction) could be related to drug craving and other withdrawal symptoms that lead to repeated drug use, but might be corrected by use of a medication that enhances dopaminergic function.

Dopaminergic medications that have been evaluated in clinical trials and found not to be effective for the treatment of cocaine use disorders include amantadine (Gawin et al. 1989b, Handelsman et al. 1995, Kampman et al. 1996, Perez de los Cobos et al. 2001), bromocriptine, (Preston et al. 1992, Eiler et al. 1995, Handelsman et al. 1997, McCance-Katz and Kosten 1998, Boyarsky and McCance-Katz 2000) methylphenidate (Roache et al. 2000), mazindol (Malson et al. 1999b, Margolin et al. 1995a, Stine et al. 1995), bupropion (Margolin et al. 1995b, Oliveto et al. 2001), flupenthixol (Evans et al. 2001, Gawin et al. 1996), haloperidol (Kosten 1997, Ohuoha et al. 1997), risperidone (Grabowski et al. 2000, 2004) selegiline (Elkashef et al. 2003) and the D1 antagonist ecopipam (Haney et al. 2001, McCance-Katz et al. 2001, Nann-Vernotica et al. 2001). Although preclinical studies implicate dopamine in the reinforcing effects of cocaine, the lack of efficacy in the many clinical trials conducted with dopaminergic agents provides indirect evidence that reinforcing effects are likely to be mediated by multiple neurotransmitters and/or intracellular processes. Indeed, cocaine is also a potent inhibitor of the reuptake of serotonin and norepinephrine (see above), either or both of which may play a role in reinforcement.

One study may indicate some utility for amantadine as a short-term initial treatment for cocaine-dependent patients with severe cocaine withdrawal symptoms (Kampman et al. 2000). In a double-blind, placebo-controlled, study of 61 cocaine-dependent individuals, those with more severe cocaine withdrawal symptoms at the beginning of the trial and who received amantadine showed greater reductions in the number of cocaine-positive urine toxicologies during treatment (Kampman et al. 2000). These results appear to be consistent with those from earlier studies indicating that amantadine might be effective in reduction of craving during the early stages of cocaine abstinence; however, the effectiveness of the medication diminishes after 3–4 weeks of treatment (Giannini et al. 1989, Kosten et al. 1992). Therefore, if this drug is to be used, the duration of pharmacotherapy treatment should not exceed 1 month. Replication of these findings would provide stronger evidence for amantadine as an initial and short-term pharmacotherapy for those with severe cocaine withdrawal.

The US National Institute on Drug Abuse (NIDA) has a medication development program for developing treatment
for cocaine abuse. One component of this effort is the Clinical Research Efficacy Screening Trial (CREST) whose goal is to rapidly identify potential treatments that should be further evaluated. Two dopaminergic agents, carbergoline (Shoptaw et al. 2005) and reserpine (Berger et al. 2005) have recently shown promise to undergo further clinical efficacy trials. These trials are still ongoing to date.

**Desipramine**
Desipramine was one of the earliest drugs explored as a potential cocaine pharmacotherapy. The rationale of using this tricyclic antidepressant as a treatment for cocaine use disorders was that desipramine treatment might reverse cocaine-induced postsynaptic dopaminergic receptor supersensitivity (McCance-Katz and Kosten 1998). Rather than acting as a general antidepressant in cocaine abusers who do not have major affective disorders, desipramine could act as a specific antianhedonic agent in this population. Whereas the positive aspects of antidepressants such as desipramine for treatment of cocaine abuse include lack of abuse liability and acceptance by patients, a significant disadvantage lies in the delayed onset of effect (approximately two weeks).

Findings from controlled clinical trials with desipramine in cocaine abusers have been mixed. An early study of 72 cocaine-abusing participants yielded encouraging results (Gawin et al. 1989a). Desipramine at dosages of 200–250 mg/day significantly decreased cocaine use. However, other clinical trials reported mixed results that were overall negative in terms of desipramine's effectiveness for the treatment of cocaine dependence (Arndt et al. 1992, Levin and Lehman 1991). In a controlled clinical trial that examined the efficacy of desipramine and psychotherapy alone or in combination as a treatment for ambulatory cocaine abusers, all groups showed significant improvement in treatment retention and a reduction in cocaine use at 12 weeks. None of the treatments, desipramine versus psychotherapy or desipramine versus combined psychotherapy and medication were clearly superior (Carroll et al. 1994a). Desipramine was more effective for subjects with lower cocaine consumption (1–2.5 g/week) or depression, indicating possible subgroups for whom this treatment might be helpful (Carroll et al. 1995b).

**Serotonergic Agents**
The rationale for the exploration of drugs with serotonergic properties as cocaine pharmacotherapies is multifold. The potency of cocaine as an inhibitor of serotonin (5-HT) uptake actually exceeds that of dopamine by twofold to fourfold (Ritz et al. 1989). Animal studies have shown that “knockout” mice lacking serotonin genes were more motivated to self-administer cocaine than normal mice and were also more sensitive to cocaine’s effects (Sora et al. 1998). It has been speculated that 5-HT may exert a dampening effect on the euphoria associated with cocaine use. Selective serotonin reuptake inhibitors (SSRIs) have been shown to displace cocaine completely from serotonergic binding sites in the hippocampus and partially displace it in the basal ganglia and cortex (Biegon et al. 1992). Despite promising preclinical findings, SSRIs, have not proven useful for the treatment of cocaine use disorders (Gonsai et al. 2002, Grabowski et al. 1995, Schmitz et al. 2001a). Focus now is turning towards other serotonergic drugs like the 5-HT₃ receptor antagonist, odansetron which is currently marketed as an antiemetic, 5-HT₃ receptors are indirect inhibitors of cortico-mesolimbic dopamine release (Bloom and Morales 1998). A 10-week, controlled, clinical pilot trial among 63 treatment-seeking volunteers revealed that the group receiving odansetron 4 mg twice daily had the lowest dropout rate among all treatment groups (0, 0.25 mg, 1 mg, or 4 mg twice daily) and a greater improvement in percentage of participants with a cocaine-free week compared with the placebo group. However, the placebo group did better than the 1 mg twice daily odansetron group suggesting a nonlinear dose-response (Johnson et al. 2006). A larger scale study with balanced treatment groups needs to be performed to confirm these findings.

**GABAergic Agents**
The neurotransmitter γ-aminobutyric acid (GABA) inhibits dopamine release and reduces the reinforcing effects of cocaine in animals (Brechner et al. 2002). Two GABAergic medications that have been evaluated in clinical trials and found not to be effective for the treatment of cocaine use disorders include gabapentin (Berger et al. 2005, Bisaga et al. 2006, Gonzalez et al. 2007, Hart et al. 2007) and valproate (Reid et al. 2005, Tennant et al. 1993. Baclofen, however, is showing some promise for the treatment of cocaine dependence. This agent is a GABA₉ receptor agonist marketed as a muscle relaxant and currently is the only specific GABA₉ compound available for human testing. Though baclofen's sedative properties complicate the interpretation of animal studies, it appears that baclofen may produce a specific attenuation of cocaine reinforcement that does not interfere with all appetitive behaviours (i.e. food-reinforced responding) (Robert et al. 1996). It is postulated that the mechanism of inhibition of drug reinforcement is in part through modulation of forebrain dopamine. In human brain imaging studies (Childress et al. 1999, 2000), experienced cocaine users were given 7–10 days of baclofen 10–20 mg twice daily to allow a gradual induction and minimize the contribution of any initial sedative effects. When compared to placebo, baclofen reduced video cocaine cue-induced craving and cue-induced activation of anterior cingulate and amygdala brain regions. Clinical studies involving baclofen have also been promising. In an open-label trial (n=10), baclofen 20 mg three times daily reduced self-reported craving and cocaine use (verified by urine toxicology) in nine of the 10 volunteers for an average of five weeks (Ling et al. 1998). Reduction in cocaine use as indicated by urine drug screening has been reported in baclofen-treated (20 mg thrice daily) patients in a randomized, placebo-controlled trial (Shoptaw et al. 2003). Collectively, preclinical and preliminary clinical study results highlight the potential for baclofen or future GABA₉ receptor agonists to be utilized as anti-relapse agents. An adequately powered clinical study needs to be performed to confirm these findings.

Tiagabine is marketed as an antiepileptic medication and acts as an inhibitor of presynaptic reuptake of GABA to increase functional GABA activity in synapses. A human laboratory study was performed in which cocaine was given in the presence of tiagabine. Tiagabine treatment did not affect cocaine-induced cardiovascular measures, but attenuated the subjective ratings of “stimulated” and “crave cocaine” (Sofuoglu et al. 2005). Additionally, a
10-week, placebo controlled clinical trial in 76 methadone-maintained, cocaine abusers found that tiagabine 24 mg/day significantly increased the proportion of cocaine-free urine samples compared to gabapentin and placebo arms (Gonzalez et al. 2007). Further clinical trials in nonmethadone maintained patients would be useful in elucidating whether tiagabine has any clinical utility as a treatment for cocaine dependence.

Two other GABAergic agents display potential and require further study. Topiramate is an antiepileptic medication that enhances GABA activity by potentiating its effect on chloride ion channels and acting as a glutamate receptor antagonist. A pilot study in volunteers who were able to remain abstinent during a two-week baseline period and then started topiramate showed reduced cocaine relapse than those randomly assigned to placebo (Kampman et al. 2004). Vigabatrin is also marketed as an antiepileptic drug outside of the US, but has not been approved in the US because of concern over visual field defects that seems to occur after long term use (Kalviainen et al. 1999, Lawden et al. 1999, Manuchehri et al. 2000, Miller et al. 1999). This agent is a selective, irreversible inhibitor of GABA transamine, a main enzyme that metabolizes GABA. Though a nine-week, follow-up, ocular safety study in cocaine and methamphetamine users did not produce any visual field defects or alterations in visual acuity (Brodie et al. 2005, Fechtner et al. 2006), larger and longer term safety studies need to be performed and an understanding of the severity and reversibility of this adverse event needs to be established in order to determine the risk versus benefits of using vigabatrin to treat cocaine dependence. At this time, vigabatrin should not be used in the treatment of cocaine dependence.

Miscellaneous Agents

Naltrexone

Naltrexone is an opioid antagonist approved for the treatment of alcohol and opiate dependence. It has also been evaluated as a possible treatment for cocaine dependence. The rationale for use of naltrexone for cocaine addiction is that opioid pathways may be important to the euphoric effect of cocaine; antagonism of this pathway might decrease the reinforcing effects of cocaine and, therefore, cocaine use (Sofuoglu et al. 2003). Results from clinical trials have been mixed. Two double-blind, randomized, placebo-controlled trials (N=90) were conducted in subjects with comorbid alcohol and cocaine use disorders using naltrexone (50 mg/day) (Modesto-Lowe et al. 1997, Hersh et al. 1998). Naltrexone was found not to be effective in reducing cocaine use or craving. In contrast, a study undertaken in the same patient population higher naltrexone dose (150 mg/day) and a longer treatment period (12 weeks) was positive (Oslin et al. 1999). The study reported that both alcohol and cocaine use was significantly reduced among those who completed the study (8 out of 15 subjects). Similar results were reported from another controlled clinical trial examining the joint action of naltrexone in combination with relapse prevention therapy (RPT) (Schmitz et al. 2001b). In this study, 85 cocaine-dependent participants who achieved initial abstinence were randomized into one of four cells: naltrexone (0 or 50 mg) and RPT or drug counseling over 12-weeks of outpatient treatment. Those receiving the combination of naltrexone 50 mg and RPT had less cocaine use than those randomized to the other conditions. Yet, a follow-up trial in dually dependent cocaine and alcohol users failed to replicate these findings (Schmitz et al. 2004) and adds to growing evidence that standard doses of naltrexone (50 mg/day) in cocaine-alcohol-dependent patients are insufficient. These conflicting results also suggest that the effectiveness of naltrexone may depend on multiple factors including other substance comorbidity, length of treatment, and type of psychotherapeutic intervention. More research is necessary to examine these factors.

Disulfiram

Numerous studies have reported results of the use of disulfiram as a treatment for cocaine dependence (Suh et al. 2006) and disulfiram has been noted as the most promising pharmacotherapy being developed for cocaine dependence (Voci and Elkashef 2005). Disulfiram, a general inhibitor of aldehyde dehydrogenases, is currently approved as a treatment for alcohol dependence. Disulfiram prevents the metabolism of acetaldehyde, an intermediary in alcohol metabolism, whose buildup produces noxious reaction when alcohol is consumed. Because disulfiram prevents the ingestion of alcohol with cocaine, a common practice of cocaine users wanting to potentiate euphoria or alleviate dysphoric and stimulant effects of binge cocaine use, it was hypothesized to be a possible treatment for cocaine dependence by preventing concomitant alcohol use. Earlier pilot studies reported that disulfiram at 250 mg/day decreased both cocaine and alcohol use (Carroll et al. 1993, Higgins et al. 1993). Human laboratory studies were undertaken in which cocaine and disulfiram were administered in combination. These studies have shown some evidence that disulfiram increases unwanted effects of cocaine (e.g., anxiety) and that a significant interaction between these two drugs occurs when cocaine is administered nasally or intravenously (Baker et al. 2007, Hameedi et al. 1995, McCance-Katz et al. 1998b). At doses of 62.5, 250 and 500 mg/day, disulfiram treatment increased plasma cocaine concentrations significantly (McCance-Katz et al. 1998b, Baker et al. 2006). However, in one study, following intravenous cocaine administration, disulfiram significantly decreased cocaine subjective effects including “any high,” “cocaine high” and ‘rush’ without significantly increasing cocaine-associated cardiovascular responses (Baker et al. 2006).

A controlled clinical trial examined disulfiram treatment alone and in combination with either cognitive-behavioral therapy or 12-step facilitation therapy. In this study of 122 patients with comorbid cocaine and alcohol dependence, disulfiram was found to be associated with better treatment retention and decreased cocaine and alcohol use (Carroll et al. 1998). The best outcomes occurred in those randomized to receive psychotherapy with disulfiram treatment. Subsequently, a 1-year follow-up evaluation was conducted with 96 participants in this study which showed that the effects of disulfiram on reductions in cocaine and alcohol use were sustained (Carroll et al. 2000). Though the number of participants that remained completely abstinent from cocaine use at 1-year follow-up were small (n = 14), 78% were receiving disulfiram. Another encouraging finding was that the initiation of abstinence for even brief periods of time within the initial treatment period was associated with significantly
better substance abuse treatment outcomes during follow-up (Carroll et al. 2000). A later study by the same researchers employed a more sophisticated design among 121 cocaine-abusing outpatients. Volunteers were randomized to one of four groups for 12 weeks for treatment: disulfiram 250 mg/day plus cognitive-behavior therapy (CBT), placebo plus CBT, disulfiram 250 mg/day plus interpersonal psychotherapy (IPT), and placebo plus IPT. Participants assigned to disulfiram reduced their cocaine use significantly more than those on placebo, and those assigned to CBT reduced their cocaine use significantly more than those assigned to IPT. Further, those who benefited the most from disulfiram plus CBT were not alcohol dependent at baseline or fully abstained from drinking during treatment (Carroll et al. 2004).

Disulfiram has also shown promise in treating opioid-dependent, cocaine abusers who are concomitantly treated with methadone or buprenorphine (Petrakis et al. 2000; George et al. 2000). In the first study, treatment medication (disulfiram 250 mg/day or placebo) for 67 volunteers was placed directly into methadone liquid daily for 12 weeks. Patients in the disulfiram group significantly reduced their frequency and quantity of cocaine use. The efficacy of disulfiram was not different between drinking and non-drinking groups, indicating a direct effect of disulfiram on cocaine intake (Petrakis et al. 2000). In 20 buprenorphinemaintained patients, treatment (disulfiram 250 mg/day or placebo) was dispensed at the same time as the buprenorphine daily for 12 weeks. Those on disulfiram achieved abstinence more quickly and remained abstinent for a greater number of weeks when compared to those on placebo. The number of cocaine-negative urine tests were also higher in the disulfiram group (George et al. 2000).

It was originally thought that disulfiram may exert its therapeutic effects by preventing alcohol use with cocaine. However, studies have shown that disulfiram efficacy between alcohol consumers and nonconsumers is similar (Carroll et al. 2004; Petrakis et al. 2000). Disulfiram may be decreasing cocaine use by inhibiting dopamine beta-hydroxylase (DBH), an enzyme that catalyzes the conversion of dopamine to norepinephrine in peripheral and central noradrenergic neurons (Vaccari et al. 1996). Inhibition of DBH results in a decrease in norepinephrine in selected areas of the brain (Goldstein and Nakajima 1967; Karamanakos et al. 2001) and leads to a corresponding increase in central levels of dopamine which may act synergistically with the unpleasant stimulant effects associated with cocaine use. This could produce an aversive response to cocaine (McCance-Katz et al. 1998b) and lead to a reduction in cocaine use. An alternative explanation for the decreased cocaine-associated effects with disulfiram treatment could lie in its effects on the serotonin system. Attenuation of positive subjective effects of cocaine with enhanced serotonin neurotransmission have been reported (Walsh et al. 1994). Cocaine alters serotonergic function by blockade of serotonin reuptake. Disulfiram might inhibit the conversion of serotonin to its principle metabolite, 5-hydroxyindoleacetic acid and lead to an increase in the metabolite 5-hydroxytryptophol (5-HTOL) (Beck et al. 1980, 1986, 1995). Increased 5-HTOL levels have been associated with adverse events including headache, fatigue and diarrhea (Helander and Some 2000). The effects of 5-HTOL in the context of cocaine ingestion might negatively impact the perception of cocaine effects and contribute to the reduction in “high” and “rush” that were observed in one human laboratory study (Baker et al. 2006). Other possible mechanisms may contribute to effects of disulfiram on cocaine responses but these have yet to be elucidated. Taken in total, these findings indicate considerable promise for the development of disulfiram in a dose range of 62.5–250 mg daily as a treatment for cocaine dependence. Further clinical trials with this medication appear warranted.

**Carbamazepine**

Carbamazepine is an anticonvulsant medication hypothesized to have potential as a therapy for cocaine abuse because of its ability to reverse cocaine-induced seizure kindling in an animal model and to reverse the dopamine receptor supersensitivity that results from chronic cocaine use (Kosten 1998). However, a recent meta-analysis conducted on five, randomized, controlled, trials with a total of 455 subjects enrolled, reported that carbamazepine is not effective in reducing cocaine use (Lima et al. 2001).

**Agonist-like, Substitution Therapy**

One approach to the treatment of drug dependence is to administer drugs that can substitute for the drug on which the patient is dependent. The best example of such treatment is that of methadone maintenance therapy for heroin/prescription opioid dependence where the physiological withdrawal associated with opioid dependence is prevented and the euphoria associated with illicit opioid administration is blocked with chronic treatment (Ling et al. 1994). This type of treatment for opioid dependence has had an important positive impact on public health. Methadone maintenance therapy has been shown to improve life functioning as well as to decrease criminal behavior and needle sharing which has been associated with increases human immunodeficiency virus risk (Ball et al. 1988; Simpson et al. 1982). As with other drugs of dependence, such as opioids and nicotine, the research of agonist-like therapy for cocaine dependence is undertaken with caution in the US where concern that this type of therapy could result in widespread abuse and pose health risks is a significant consideration. However, several substitution medications for stimulant dependence have been evaluated in preclinical and clinical trials (Grabowski et al. 2004).

Oral formulations of cocaine (i.e. tea infusions, tablets) have been studied in Peru for coca paste smokers with overall results showing a significant reduction in relapse to heavy use and cravings (Llosa 1994, 1996). Additionally, in a phase II clinical trial, oral cocaine was administered over a range of doses (0–100 mg/day) for ten days (Walsh et al. 2000). Researchers found that oral cocaine modestly attenuated subjective and physiological responses to intravenous cocaine challenges. Similar results were produced in another study in which intravenous cocaethylene, a pharmacologically active cocaine homolog formed by transesterification of cocaine in the presence of alcohol, was given over 6 hours before a cocaine challenge was administered (Baker et al. 2006). No adverse cardiovascular effects were reported. Cocaethylene has been found to have a longer half-life relative to cocaine (Hart et al. 2000), an important factor in medications development since the drug might lend itself to
a formulation that might be administered conveniently (e.g., once daily or less frequently).

Dexamphetamine (also known as dextroamphetamine and d-amphetamine), a drug marketed for attention-deficit hyperactivity disorder and narcolepsy has shown modest positive results for the treatment of cocaine dependence in three clinical trials. In one 14-week placebo-controlled study, 30 cocaine-dependent participants were assigned 60 mg/day dexamphetamine or placebo (Shearer et al. 2003). Retention was equivalent between the two treatment groups. However, dexamphetamine reduced cocaine use, criminal activity, cocaine cravings and signs of dependence when compared to the placebo group. In another 13-week, double-blind, placebo-controlled, trial \( n = 114 \), cocaine positive drug screens were reduced with increasing dexamphetamine doses (15 mg/day titrated to 30 mg/day versus 30 mg/day titrated to 60 mg/day), though results were not statistically significant (Grabowski et al. 2001). A later 26-week \( n = 94 \) study by the same group treated cocaine- and heroin-dependent volunteers with methadone and varying doses of dexamphetamine (0–60 mg/day) and found that cocaine intake significantly declined in the 30–60 mg/day group compared to the lower dose and placebo groups (Grabowski et al. 2004). With the exception of one case of psychosis (Shearer et al. 2003) in a participant who concurrently used methamphetamine and who had not disclosed a history of drug-induced psychotic episodes, there were no other reported cardiovascular or psychiatric adverse events in these three clinical trials.

Modafinil is a stimulant-like medication marketed for the treatment of excessive sleepiness. The mechanism of action of this agent is controversial and currently remains not fully understood. It has been shown that modafinil promotes feelings of well-being (Beusterien et al. 1999) and has stimulatory effects that are largely opposite to cocaine withdrawal symptoms. Abuse liability studies have shown that abuse potential is modest (Basinski 2000, Rush et al. 2002, Warot et al. 1993), therefore making modafinil an important candidate as a substitution treatment for cocaine dependence. Case reports of stimulant abusers treated with modafinil have shown decreased craving for amphetamines and another one decreased craving and less use of cocaine (Malcolm et al. 2002). A double-blind, placebo-controlled, cocaine challenge study with modafinil 200 and 400 mg/day was performed in seven nontreatment-seeking-cocaine-dependent volunteers (Dackis et al. 2003). No additive effects between cocaine and modafinil on cardiovascular parameters were noted and subjects reported attenuation of cocaine effects on the Addiction Research Center Inventory (ARCI) Amphetamine Scale (a measure of drug euphoria). Another cocaine challenge study in 12 cocaine-dependent individuals identified no harmful pharmacokinetic interaction between modafinil and cocaine (Donovan et al. 2005) and though this was an open-label study, found that modafinil significantly dampened Visual Analog Scale measures of cocaine effects (Malcolm et al. 2006). To date, one randomized, double-blind, placebo-controlled, pilot study examining the efficacy of modafinil among 62 cocaine-dependent outpatients has been published (Dackis et al. 2005). Patients receiving modafinil 400 mg/day for eight weeks provided significantly fewer urine samples positive for cocaine metabolite and were more likely to achieve a protracted period of cocaine abstinence when compared to those on placebo. However, the results from this trial are conflicted as there was no significant modafinil effect on the rate of patient-reported cocaine use. Possibilities for these findings might possibly include dilute urine samples that did not show the presence of cocaine metabolite or urine testing not coincident with participant drug use, as well as a problem with the assay itself. Further well-designed research is warranted in order to determine whether modafinil may have efficacy in the treatment of cocaine dependence.

**Ongoing Medications Development for Cocaine Use Disorders**

Medications development continues for cocaine use disorders. Several novel approaches have been discussed in the literature and some clinical trials are ongoing. A cocaine vaccine is being developed that may reduce or halt cocaine abuse. The vaccine is structurally similar to cocaine, but is coupled to a carrier protein that prevents rapid metabolism, thus making it possible to mount an immune response to cocaine by sequestering cocaine molecules in the bloodstream and preventing cocaine entry to the brain, thus preventing cocaine-associated euphoria and reinforcement (Fox 1997, Martell et al. 2005). Animal studies have shown that the anti-cocaine vaccine effectively blocked physiological and behavioral effects of cocaine (Carrera et al. 2000, 2001, Fox et al. 1996, Kantak et al. 2000, 2001). Further, the efficacy of the vaccine in preventing cocaine self-administration was examined using a rat model for cocaine relapse (Carrera et al. 2000). As compared to controls, vaccinated animals did not reinstate cocaine self-administration behavior when given a noncontingent cocaine infusion on two consecutive days. Upon double and triple infusions, 38–62% of vaccinated animals did not reinstate cocaine self-administration as compared with cocaine self-administration reinstatement in all control animals (Carrera et al. 2000). Initial human studies have shown the cocaine vaccine to have no serious adverse effects during 12 months of follow-up and confirm that it does induce cocaine-specific IgG cocaine antibodies in a time and dose dependent manner (Kosten et al. 2002, Martell et al. 2005). The most recent human trial examined initial efficacy of the vaccine and found that the higher dose vaccine \( 2000 \text{ mcg} \) was more likely to maintain cocaine-free urines than the lower dose \( 400 \text{ mcg} \). Of those in both groups who used cocaine during a 14-week study interval, 100% reported diminution of cocaine’s euphoric effects. At six months, 89% of the low dose and 43% of the high dose group had relapsed, but the majority of volunteers (> 60%) continued to report attenuation of cocaine’s euphoric effects (Martell et al. 2005).

Unlike typical antibodies, catalytic antibodies can selectively catalyze cocaine molecules via a wide range of reactions, from hydrolysis of esters and amides to pericyclic reactions (Cashman et al. 2000, Lerner et al. 1991, and Schultz and Lerner 1995). In rodent studies, catalytic antibody administration blocked toxicity of cocaine in rats and blocked cocaine reinforcement (Mets et al. 1998). This approach could provide a new and effective treatment for acute cocaine intoxication, but no human studies have yet been performed.

Acupuncture is an ancient Chinese therapy that may hold promise for treatment of cocaine use disorders. Earlier studies of acupuncture in cocaine addiction treatment
suffered from the lack of a rigorous scientific design and were inconclusive. One well-designed study with an active acupuncture control procedure found that the patients who received acupuncture were more likely to be free from cocaine use during an eight-week study period than were control subjects as measured by cocaine-negative urine toxicology samples (Avants et al. 2000). However, a very large follow-up study by these same researchers did not have encouraging results for the use of acupuncture alone to treat cocaine dependence. This study was performed throughout 6 community-based clinics in the US and enrolled 620 cocaine-dependent patients. Volunteers were randomly placed in one of three groups: acupuncture, a needle-insertion control, or a relaxation control. Treatments and concurrent counseling were offered five times weekly for eight weeks. Counseling sessions were poorly attended and there was no difference between conditions based on urine samples or treatment retention (Margolin et al. 2002). A subsequent smaller study did show that adding spirituality focused group therapy to acupuncture was more beneficial than acupuncture alone (Margolin et al. 2005). However, there was not a spirituality focused group therapy alone condition in this study. At this time there is no evidence to support the use of acupuncture alone for the treatment of cocaine dependence.

**Common Problems in Management**

Several common problems are encountered in the treatment of patients with cocaine use disorders. These include (1) relapse to cocaine use, (2) comorbid psychiatric disorders, (3) comorbid substance use disorders, (4) premature treatment termination, and (5) treatment refractoriness.

**Relapse to Cocaine Use**

The psychological addiction to cocaine is powerful and the risk for relapse to cocaine use is high during treatment. This is particularly true in outpatient treatment settings when patients are often subject to exposure to the persons, places, and things that remind them of their cocaine use which can induce strong craving. Patients who are recently abstinent are at high risk for relapse because they often experience dysphoria with the cocaine withdrawal syndrome and contrast that mood state with the memory of cocaine-induced euphoria, which can be overwhelming and precipitate a new cycle of cocaine abuse. Patients early in the treatment process have not developed the coping skills that might help them to overcome drug craving and have not experienced success in remaining abstinent which is also important to helping the patient to gain control over cocaine craving.

It is important to discuss the risk of relapse with patients in cocaine treatment in general terms and to specifically address the concerns of individual patients regarding their relapse potential. This can provide the basis for building a repertoire of coping skills and assist with processing a relapse, should it occur, in a therapeutic manner. For outpatient patients who are unable to initiate and maintain abstinence, consideration of a higher level of care such as a partial hospital program, day treatment program, or a long-term program (e.g., therapeutic community) is appropriate.

**Diagnosis of Other Mental Disorders**

The diagnosis of comorbid mental disorders can be difficult in the presence of cocaine use disorders. Affective and psychotic symptoms are common during cocaine intoxication. Affective symptoms may continue for weeks to several weeks following the initiation of abstinence. In addition, abuse of and/or relapse to cocaine and/or other illicit drug use is common and can exacerbate psychiatric symptoms. It can be difficult to determine whether psychiatric symptoms represent a comorbid psychiatric disorder, an extended withdrawal syndrome, or the continuation of substance abuse. In general, affective and psychotic symptoms that occur during intoxication remit within hours to days of cessation of cocaine use and require limited use of psychotropic medication. Affective symptoms related to cocaine withdrawal may continue for weeks, but generally improve over time and are not severe enough to meet criteria for a specific Axis I disorder such as major depressive episode. The patient whose psychiatric symptoms worsen despite treatment for cocaine use disorders, and in whom regular (2–3 times weekly) urine toxicology screens reveal continued abstinence is likely to have a comorbid psychiatric disorder and should receive appropriate psychiatric treatment. Those with a history of a well-documented psychiatric disorder that has occurred in the absence of drug abuse or predated the substance use disorder should also be observed closely for the development of a comorbid psychiatric illness during treatment with psychiatric intervention as needed. It is important to note, however, that the previous diagnosis of a mental illness in a person with a cocaine use disorder (or other substance use disorders), may not be accurate. Previous diagnoses made in the context of recent cocaine abuse or during withdrawal may actually reflect psychiatric symptoms related to cocaine intoxication or withdrawal. Careful evaluation of the patient at the time of presentation is needed to determine the presence of a comorbid psychiatric disorder regardless of prior diagnoses unless the patient has well-characterized mental illness and/or is known to the clinician. Common misdiagnoses include bipolar disorder, major depression, schizoaffective disorder, attention deficit hyperactivity disorder, generalized anxiety disorder, and panic attacks. While these disorders can be present concomitantly in those with cocaine use disorders, the overlap of symptoms between these mental disorders and those related to cocaine abuse mandate the careful evaluation of every patient known to have a cocaine disorder prior to making the diagnosis of a comorbid mental illness.

**Comorbid Substance Use Disorders**

Abuse of or dependence on other illicit drugs or alcohol is common in patients with cocaine use disorders. It has been reported that 62–90% of cocaine abusers are also alcohol abusers and simultaneous use of these substances is common (Brokoff et al. 1996, Grant and Harford 1990, Heil et al. 2001, McCance-Katz et al. 1993). Cocaine abusers report that simultaneous use of alcohol can prolong euphoric effects and relieve the negative effects of binge cocaine use including stimulant effects such as anxiety, agitation, and paranoia, or to decrease acute abstinence symptoms (Hart et al. 2000, McCance et al. 1995). Opiates and benzodiazepines serve this purpose for some with primary cocaine use disorders, but this is less common. However, cocaine abuse by opiate dependent persons is common and may enhance or alter opiate-induced euphoria (e.g., heroin and cocaine taken simultaneously is termed a “speedball”)

**Chapter 58 • Substance Abuse: Cocaine Use Disorders**

1077
or decrease the sedative effects of opiates (Grella et al. 1997, Mello and Negus 2001, Negus et al. 1998). It is important to establish whether patients presenting for treatment also abuse other substances such as alcohol or opiates because physical dependence on these substances is common and may require medical withdrawal. If there is dependence on other drugs or alcohol, the medical withdrawal process should proceed prior to initiation of cocaine abuse treatment to ensure medical safety and optimize the possibility of effective treatment of the cocaine use disorder.

Patients presenting for treatment of cocaine use disorders must have a full evaluation with urine drug screen to determine current use of other drugs. An alcohol breath test (Breathalyzer) can be used to detect recent alcohol use and a urine test for ethyl glucuronide is now available and shows evidence of alcohol use for up to four days (Wurst et al. 2003). Laboratory findings including liver function (ALT, AST) and mean corpuscular volume (MCV) and carbohydrate deficient transferrin (Bortolotti et al. 2006) can also be helpful in the assessment of alcohol abuse.

The treatment of comorbid substance use disorders is important because continued abuse of other substances is associated with relapse to cocaine abuse. Treatment of comorbid substance use disorders can be integrated into the treatment program for cocaine abuse. Psychotherapies effective for cocaine abuse are also effective for other abused substances and individuals with comorbid disorders can address multiple substance use problems in individual and group counseling formats. Pharmacotherapies for other substance use disorders can be undertaken in conjunction with cocaine abuse treatment as well. For example, nicotine replacement therapy or naltrexone or disulfiram for alcohol use disorders can be a part of the individualized treatment plan for patients with cocaine abuse and nicotine dependence or alcohol dependence, respectively.

Cocaine–Alcohol Abuse and Cocaethylene
Simultaneous abuse of cocaine and alcohol occurs frequently. One consequence of the coabuse of these substances is the formation of cocaethylene. Cocaethylene is a pharmacologically active homolog and metabolite of cocaine, formed by transesterification of cocaine in the presence of ethanol. Cocaethylene and cocaine share pharmacological characteristics in blocking dopamine uptake, inhibiting ligand binding to the dopamine transporter, and increasing dopamine concentration in brain microdialysate. Cocaethylene has less effect on serotonin and norepinephrine transporters than does cocaine (Bradberry et al. 1993, Henning and Wilson 1996, Jatlow et al. 1991, McCance-Katz et al. 1993). Although cocaethylene is equipotent to cocaine as a reinforcer in animals, it is less potent than cocaine in humans and has a longer elimination half-life than cocaine (Hart et al. 2000, McCance et al. 1995). However, the effects of cocaine, alcohol, and cocaethylene in combination could produce increased toxicity in co-abusers of these substances (Jatlow et al. 1991, McCance-Katz et al. 1998a, 2001). Because of this, it is important to recognize and provide treatment for cocaine and alcohol abuse when they occur simultaneously.

Premature Treatment Termination
Premature treatment termination or treatment dropout is common in patients with cocaine use disorders. The most common reason for this occurrence is relapse to cocaine use. Patients are at especially high risk for relapse at the early stages of treatment when craving is most severe and coping skills and support systems are poorly developed. Addressing this possibility from the initial contact with the patient can be helpful in that it provides the patient with an understanding of what difficulties to expect in the process of abstinence initiation. In addition, discussion of the possibility of relapse and the potential for leaving treatment can also be used to help the individual develop a plan for preventing this occurrence, which will improve the chance that the patient will ultimately be successful in treatment. Processing previous treatments and reasons for failure early in treatment can be helpful in determination of what level of care is most appropriate for the patient.

Treatment Refractoriness
The term “treatment refractoriness” sometimes implies a lack of response to a therapeutic trial of a pharmacotherapy. In the case of cocaine dependence, however, there is no FDA-approved, effective pharmacotherapy with which to treat the disorder, therefore, the term relates to a different set of occurrences in the treatment setting. Recidivism to cocaine use, treatment dropout, and multiple treatment experiences are common. Such problems are a reflection of the severity of illness and parameters of relative treatment refractoriness. Comorbid substance use and psychiatric disorders contribute to treatment refractoriness. Lack of accurate diagnosis and treatment contributes to relapse potential in the form of continued exposure to high-risk situations and lifestyle instability that are associated with ongoing substance abuse. Continued psychiatric symptoms that patients attempt to relieve through cocaine use contribute to poor treatment outcome.

The psychological addiction associated with cocaine abuse can be disabling. Because physiological dependence, if it does occur, generally does not require pharmacotherapy, treatment referrals for patients with primary cocaine dependence, and no other acute medical or psychiatric condition, are generally to an outpatient drug abuse treatment clinic. Those unable to initiate and maintain sobriety in an outpatient drug treatment program should be evaluated for more intensive forms of treatment. Management of these individuals should include consideration of a variety of options including pharmacotherapy (see the earlier section on pharmacotherapy for cocaine abuse) and programs that offer a graded increase in structure. Such patients may need initial detoxification from another drug or alcohol that could require several days of inpatient treatment. Those who need intensive outpatient treatment often attend 5 days a week initially, and sessions last an average of 4 hours. There is a gradual reduction in the number of sessions per week as the period of sobriety lengthens. Such programs are of flexible duration but a full program usually requires at least 12 weeks. This program can be followed with resumption of the outpatient treatment clinic level of care, which takes place fewer days per week and with shorter sessions. Those with comorbid psychiatric disorders should be referred to specialty treatment programs that address both substance use disorders and mental illness. These programs differ from traditional substance abuse treatment programs in that they have a dual treatment orientation, increased use
of psychotropic medications, longer lengths of stay, and greater tolerance for relapse and medication nonadherence. As compared to standard drug abuse treatment programs, they tend to have a more severe case mix, a higher 180-day readmission rate, and a higher rate of psychiatric aftercare in the 30 days after discharge (Swindle et al. 1995).

Patients who have failed other forms of treatment may be referred to residential programs. Residential programs vary in length and must be tailored to the needs of the patient. Such programs can be important to the initiation of abstinence. These programs allow sufficient time in a drug-free and supportive environment so that the recovery process can begin, as well as provide adequate time for reduction of drug craving and acquisition of effective relapse prevention skills.

**Psychiatric Comorbidity**

Treatment-seeking cocaine abusers have significant rates of psychiatric disorders (Carroll et al. 1997). Cocaine abuse may adversely affect the psychiatric disorder, with the occurrence of symptoms of psychosis, depression, or suicidal ideation that worsen during the course of cocaine use (Dixon 1999, Roy 2001, Schmitz et al. 2000, Serper et al. 1999). Patients with underlying psychotic disorders may exhibit exacerbation of psychotic symptoms in response to stimulants at doses that would not be psychotogenic in those without psychotic disorders or vulnerability to psychotic disorders (Yui et al. 1999). Those with psychotic disorders need pharmacological management and often require hospitalization as a result of exacerbations of the mental disorder that occur with cocaine abuse (Buckley 1998). Furthermore, those with comorbid psychiatric disorders complicated by substance abuse often require increased doses of psychotropic medications to control symptoms.

The diagnosis of comorbid psychiatric disorders in cocaine abusers is often challenging because the onset of many such disorders occurs in adolescence or early adulthood, the same period as for the onset of cocaine addiction. This makes determination of primary versus secondary diagnosis difficult. However, careful developmental and family histories and attention to the presence or absence of psychiatric symptoms during periods of sobriety can be helpful and may assist in diagnostic accuracy which is essential to providing adequate treatment. Worsening psychiatric symptoms in the context of abstinence from cocaine is also an indication of the presence of a concomitant mental illness.

Symptoms associated with substance use disorders, including acute intoxication and withdrawal syndromes, may be mistaken for mental illness, resulting in misdiagnosis and inappropriate psychiatric treatment that usually includes psychototropic medication. This can foster denial in that substance abusers who sometimes attribute drug abuse to a psychiatric or emotional problem leading to resistance to treatment for the substance disorder. Denial of a substance disorder when it is, in fact, the correct underlying diagnosis, results in ineffective treatment and continued drug abuse. The pervasive nature of substance use disorders requires increased emphasis on substance abuse education for mental health providers, attention to substance abuse in the history taking and ongoing treatment, and urine drug screens as a routine part of treatment. It is important to understand that treating a mental illness in a patient with both a substance use disorder and mental illness will not provide effective treatment for the substance use disorder. Conversely, treatment of only the substance use disorder in a patient with comorbid disorders will not effectively treat the mental illness. Such patients must receive concurrent treatment for substance use disorders and mental disorders.

**Comorbid Mood Disorders or Attention Deficit Hyperactivity Disorder**

Comorbid mood disorders and residual attention deficit hyperactivity disorder (ADHD) may occur in cocaine abusers (Biederman et al. 1999). Lifetime prevalence of mood and anxiety disorders among those with cocaine use disorders in treatment have been reported to be as high as 48% for men and 70% for women (Brady and Randall 1999). Depressive disorders have been some of the most commonly diagnosed comorbid disorders among those with cocaine use disorders (Brown et al. 1998, Compton et al. 2000). Those diagnosed with cocaine use disorders and depression have greater overall distress and poorer functioning than those without depression (Schmitz et al. 2000). Lifetime prevalence of major depressive disorder has been shown to be significantly correlated with suicide attempts in those with cocaine use disorders.

Several lines of evidence point to the integral relationship of depression to cocaine use disorders. First, the symptoms associated with the cocaine withdrawal syndrome are similar to those observed in depressive disorders (Uslaner et al. 1999). Second, lifetime years of cocaine use is one of the major predictors for depression among cocaine users (McMahon et al. 1999). Third, severity of depressive symptoms in treatment-seeking cocaine abusers is associated with poorer treatment retention, greater urge and craving, and more intensive response to cocaine effects (Brown et al. 1998, Sofuoglu et al. 2001, Uslaner et al. 1999). These findings support the need for more intensive treatment approaches for patients with comorbid disorders. Antidepressant treatment is an important component of treatment for those with comorbid disorders. While antidepressants provide effective treatment for reduction of depressive symptoms, they have little effect on cocaine use (Carroll et al. 1997, Schmitz et al. 2001a). It is also worth mentioning that while comorbid depression may complicate diagnosis and treatment regimen in this population, neither a diagnosis of depression nor severity of depressive symptoms predicts treatment outcome (Brown et al. 1998).

Children with ADHD have been shown to have an increased risk of developing cocaine and other substance use disorders (Clure et al. 1999, Levin et al. 1998a, Schubiner et al. 2000). While methylphenidate is the most effective treatment for ADHD (Jensen 2000, Smith et al. 2000), many clinicians fear that methylphenidate treatment for those with comorbid ADHD and substance use disorders may increase the risk of substance abuse, particularly stimulant abuse. However, a longitudinal study has shown that treating children diagnosed with ADHD with stimulant medications, including methylphenidate, reduced the risk of substance abuse and dependence by 84% (Biederman et al. 1999). In addition, clinical reports have indicated that methylphenidate is effective for treating ADHD in those with cocaine dependence (McCance-Katz and Schottenfeld...
Clinical trials, however, investigating the efficacy of methylphenidate for the treatment of cocaine dependence and ADHD have shown mixed results. A pilot study showed that methylphenidate treatment for those with comorbid ADHD and cocaine abuse reduced ADHD symptoms, cocaine use, craving, and positive urine toxicologies for cocaine (Levin et al. 1998b). A larger 14-week study by the same researchers involved 106 participants (Levin et al. 2007). This placebo-controlled, double-blinded study found no difference in retention rate and improvement in ADHD symptoms between treatment groups. Yet, further analyses revealed that among ADHD treatment responders, those receiving methylphenidate were associated with a reduction in cocaine use compared to those receiving placebo. Another placebo-controlled, double-blinded, study in 48 dually diagnosed volunteers found an improvement in ADHD symptoms in the methylphenidate group, but no between-group difference in cocaine use or cravings (Schubiner et al. 2002).

Antisocial Personality Disorder

Another psychiatric disorder common in cocaine abusers is antisocial personality disorder (Compton et al. 2000). Identification of this disorder is important because it is associated with poor treatment outcome in those with cocaine use disorders. There is no clear indication for use of pharmacotherapy in patients with antisocial personality disorder. If pharmacotherapy for a cocaine use disorder were to be considered, it would be best to stabilize the patient for several weeks and monitor symptoms carefully to determine need for medication treatment.

Psychotic Disorders

Cocaine abuse is widely recognized as a significant clinical problem in patients with schizophrenia with a reported prevalence of 15–60% (Buckley 1998, Dixon 1999, Mauri et al. 2006, Swartz et al. 2006). Cocaine use may hasten the onset of a psychotic disorder in a vulnerable patient and may exacerbate the course of the illness by precipitating psychotic relapse (Volkow 2001) or by causing depression, anxiety, insomnia, agitation, or aggressiveness (Buckley 1998, Serper et al. 1999). Comorbid substance use disorders in those with psychotic disorders are associated with a variety of poor outcomes, including increased psychotic symptoms, poor treatment compliance, violence, medical illness (e.g., HIV infection), and poor social function that result in a higher cost of medical/psychiatric care (Dixon 1999). These findings underscore the need to integrate substance abuse treatment and psychiatric care for this population. Cocaine and other substance abuse usually persist despite treatment with antipsychotic medications. The efficacy of newer atypical antipsychotic medications for reduction of substance abuse among the schizophrenic population is yet to be established, but clozapine has been shown to reduce alcohol, smoking, and cocaine use (Zimmet et al. 2000). However, clozapine has been associated with cardiovascular side effects including near-syncopy in those pretreated with clozapine and then administered cocaine in a laboratory setting (Farren et al. 2000, Zimmet et al. 2000). These findings contraindicate the use of clozapine in those with cocaine use disorders. Patients with schizophrenia who adhere to antipsychotic medications and remain in treatment have higher levels of abstinence and fewer days of hospitalization (Bennett et al. 2001, Dixon 1999, Krystal et al. 1999, Zimmet et al. 2000). Taken together, these findings highlight both the detrimental influence of cocaine abuse on the course of schizophrenia and the possibility that cocaine abuse may cause and/or perpetuate a psychotic disorder closely resembling schizophrenia. Specialized dual-diagnosis treatment programs that attend to both the psychiatric and substance use disorders in these patients have shown promising results and should be used when available for the treatment of these severely ill patients (Bennett et al. 2001, Krystal et al. 1999, Martino et al. 1995).

Clinical Vignette 1

Mr. A, a 22-year-old man, was admitted to an outpatient clinic for treatment of cocaine dependence. He reported a 3-year history of cocaine abuse and intranasal use of cocaine daily for several months before seeking treatment. The patient maintained abstinence during the initial weeks of treatment, but complained of difficulty sitting still in groups and poor concentration. He also described a calming effect of cocaine on these chronic problems, which contributed to intensified drug craving. A psychiatric evaluation revealed a developmental history consistent with attention-deficit hyperactivity disorder (ADHD). The history of residual symptoms was also confirmed by the patient’s significant other.

A trial of methylphenidate was initiated at 10 mg/day and increased to a dosage of 20 mg/day. Mr. A reported feeling calmer and better table to concentrate, with decreased cocaine craving. When methylphenidate was increased to 30 mg/day, Mr. A complained of abdominal discomfort and irritability in the evening, which reminded him of cocaine withdrawal symptoms. Although it was recommended that the dose be reduced to 20 mg/day, the patient was anxious about the occurrence of these symptoms and requested that the medication be discontinued because he feared relapse. Within several days of stopping the medication, the unwanted symptoms abated, but the ADHD symptoms returned. A trial of atomoxetine was initiated with titration to 80 mg/day with no reported side effects. The patient reported improvement in concentration and decreased motor activity. He continued outpatient treatment in a partial hospital program with a specialized track for those with mental illness and self-help groups.

Final DSM-IV-TR Diagnoses

Axis I: Cocaine dependence, Attention-Deficit/ Hyperactivity Disorder

Axis II: Deferred

Axis III: None

Clinical Vignette 2

Mr. B is a 34-year-old divorced man with a 10-year history of freebase cocaine abuse characterized by weekly binge use of up to 6 g of cocaine and alcohol use reported as five beers several times per week with cocaine, but no other illicit drug use. He was admitted to the hospital emergency department with a chief complaint of visual hallucinations and paranoid ideation that developed (continues)
Clinical Vignette 2 continued

during the course of several hours of binge cocaine use. On physical examination, he was noted to be agitated with mild tachycardia and hypertension, but there were no other concurrent medical illnesses.

Haloperidol 5 mg and lorazepam 2 mg were administered by intramuscular injection for treatment of psychosis and agitation, with rapid abatement in symptoms. The patient was transferred to an inpatient unit for further evaluation. Resolution of visual hallucinations and paranoia occurred within 24 hours. After two days of hyperosmia, intermittent anxiety, and mild depressive symptoms, he reported feeling better and began to engage in substance abuse treatment. He was discharged to an outpatient clinic for further treatment of cocaine and alcohol use disorders.

Final DSM-IV Diagnoses

Axis I: Cocaine dependence, alcohol abuse, cocaine intoxication, cocaine withdrawal
Axis II: Deferred
Axis III: None

Clinical Vignette 3

Ms. C. is a 25-year-old, single woman with a 2-year history of binge cocaine use by the smoked route of administration. In the past four months, she has increased her use of cocaine from once weekly to up to three binges weekly. Following a 12 hour binge, she presents to the emergency department complaining of depression, suicidal thoughts, poor concentration, and feelings of paranoia. She is agitated and tearful. She is admitted to the psychiatric inpatient unit for further evaluation and treatment. For the first two days, she is hypersomnolent and hyperphagic. She is isolative and appears depressed. By day five she is participating actively in unit therapies and is no longer suicidal. The treatment team refers her to ongoing outpatient substance abuse treatment. Final DSM-IV TR Diagnoses:

Axis I: Cocaine Dependence, Cocaine Withdrawal, Cocaine-Induced Mood Disorder
Axis II: Deferred
Axis III: None.

Comparison of DSM-IV/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR Criteria sets for Cocaine Intoxication and Withdrawal are similar except that the ICD-10 criteria set for Withdrawal includes drug-craving as an additional item.

Phencyclidine (1-(1-phenylcyclohexyl)piperidine) (PCP) was developed as a general anesthetic agent in the 1950s under the brand name Sernyl (Collins et al. 1960, Greifenstein et al. 1958, Johnstone et al. 1958). The drug was considered physiologically promising because of its lack of respiratory and cardiovascular depressant effects. In fact, patients under PCP anesthesia, rather than manifesting a state of relaxed sleep such as that induced by typical anesthetic agents, appeared semiconscious, with open eyes, fixed staring, flat facies, open mouth, rigid posturing, and waxy flexibility. Because of this apparent sharp dissociation from the environment without true unconsciousness, PCP and the related drug ketamine were classified as dissociative anesthetics (Corssen and Domino 1966).

Approximately 50% of patients anesthetized with PCP developed behavioral syndromes including agitation and hallucinations during emergence from anesthesia (Collins et al. 1960, Greifenstein et al. 1958, Johnstone et al. 1958). A substantial number of subjects developed postoperative psychotic reactions, which in some cases persisted up to 10 days (Greifenstein et al. 1958, Johnstone et al. 1958, Corssen and Domino 1966, Meyer et al. 1959). Trials of subanesthetic doses of PCP for treatment of chronic pain led to similar although less severe adverse reactions (Meyer et al. 1959). As a result, after 1965, PCP was limited to veterinary applications. Ketamine remains available for human anesthesia; side effects are less frequent and severe owing to the lower potency and shorter duration of action of ketamine compared with PCP.

Despite its well-documented aversive and disruptive behavioral effects, PCP emerged during the 1970s as a popular drug of abuse, increasing in popularity to the point that in 1979, 13% of high-school seniors had tried it (Johnston et al. 1994). Although PCP has never regained that remarkable level of popularity, it has remained a significant public health problem among certain populations and in certain geographical areas. Compared with most other drugs of abuse, PCP has more complex and potentially more harmful effects.

**Epidemiology**
Illicit use of phencyclidine was first noted in 1965 in Los Angeles (Lerner and Burns 1978). The spread of the drug from California throughout the country was facilitated by its ease of synthesis compared with other drugs. At least six synthetic methods, some simple, are published in scientific journals (Allen et al., 1993). Surveys of street drug samples indicated that PCP was sold under many street names (Table 59–1) and frequently combined with or misrepresented as other substances (Lerner and Burns 1978, Siegel 1978). During the late 1970s and early 1980s, PCP gained considerable notoriety in the popular press not only as a leading drug of abuse but as one with particularly novel and devastating effects.

According to trends in emergency department visits, deaths, initiates entering drug treatment programs, and surveys, PCP abuse increased through the 1970s, peaked in 1978 to 1979, and then declined sharply through 1981, when indicators began to show a new increase through 1984 (Crider 1986). The decline in PCP use during the late 1970s and early 1980s may have resulted in part from a variety of public health and law enforcement activities, including a nationwide education campaign aimed at informing treatment programs, emergency departments health agencies, and medical examiner–coroner offices of PCP effects and treatment procedures. PCP was rescheduled from Schedule III to the much more restrictive Schedule II of the Controlled Substances Act.
Clinical Vignette 1

A 22-year-old single man was brought to the emergency department by a friend who left without providing any information. The patient was severely agitated and hypervigilant, repeatedly looking over his shoulders and patrolling the examination room. Asked to explain, he said, “I’m scared. Something is after me. I can’t say anything else.” He was unable or unwilling to give any history. Vital signs and neurological examination findings were within normal limits. A urine sample was sent for qualitative toxicological analysis. The result, received 5 days later, was positive for PCP. His condition remained unchanged during 3 hr of observation in the emergency department. He spontaneously went to the telephone and called the friend who had brought him to the hospital but found himself unable to speak. He handed the telephone to the emergency department physician, who was able to obtain from the friend the information that the patient had smoked three PCP-impregnated marijuana cigarettes in a 12-hr period beginning 18 hr before admission. The friend stated that this had been the patient’s first exposure to PCP: “He got scared and bummed out and begged me to take him to the hospital.” A mental status examination revealed impaired attention and memory, with concrete interpretation of proverbs. He continued to complain of being frightened and to survey his surroundings continuously, saying, “I have to watch out or I could get hurt.” He admitted to feeling in great danger from forces outside himself. He denied hallucinations. It was noted that the patient became more agitated after interviews or clinical interventions.

He was admitted to the psychiatry service, where treatment was initiated with haloperidol 2 mg three times a day, increasing to 5 mg three times daily by the third day. His mental status remained essentially unchanged from that observed in the emergency department until the end of the third week after admission, when he reported having intervals when he felt less agitated and free of his feelings of persecution. According to the staff, however, at times he was still observed looking back over his shoulder and muttering to himself. His nonpsychotic intervals gradually became more frequent. At the end of the fourth week, he began interacting with staff and visitors and participating in groups and other ward activities. At the beginning of the sixth week, mental status examination revealed no evidence of psychosis. Neuroleptic medication was discontinued without relapse. He gave a history of sporadic abuse of marijuana and cocaine during the previous 3 years. He contacted his parents, who traveled from the distant state in which they lived to participate in treatment and discharge planning. He was discharged directly to a long-term residential drug treatment program. Contacted 1 year later, he was living with his parents in the other state, participating in Narcotics Anonymous, and stated that he had been drug free since discharge from the hospital. He added, “Even if I ever use drugs again—and I hope I won’t—I would never, ever use PCP.”

Comment

This clinical vignette illustrates a purely psychiatric presentation of PCP psychosis, with no physical or neurological symptoms or signs 6 hr after the last dose of drug. Without the history obtained from the friend, the correct diagnosis would not have been made until the toxicology results were received. All of the patient’s symptoms could have been accounted for by a non–drug-related psychiatric illness. The failure of the psychotic symptoms to respond to neuroleptic medication, and the patient’s recovery by the sixth week, are typical of the prolonged PCP psychosis in an otherwise nonpsychotic individual.

Substance Act on the basis of its limited legitimate uses and significant abuse potential. Several PCP analogues were placed in Schedule I. Required reporting of production of the precursor, piperidine, began in 1979; penalties for possession of PCP with intent to sell were increased at about the same time (Crider 1986).

In more recent years, indicators of PCP use have remained generally low; however, localized increases have been observed, in some cases associated with the use of new dosage forms (in particular, the use of “blunts,” cigars filled with PCP-impregnated marijuana) (Community Epidemiology Work Group 1994).

As of 2006, the highest rates of PCP use during the past year were observed among 18–20-year-olds, followed by 12–17, 21–25, and 26–34-year-olds. 2.4% of high school seniors endorsed lifetime abuse and 0.7% endorsed past-year abuse (Johnson et al. xxxx). Rates were increased from 2004, but generally stable from rates since 1991. In 2005, among Americans aged 12 or older, it was estimated that 48,000 had used PCP within the past month, 164,000 within the past year, and 6,603,000 (2.7% of the population) within their lifetimes. These rates were stable from the year prior (Substance Abuse and Mental Health Services Administration 2001). In 2005, PCP misuse/abuse was detected in 7,535 Emergency Department visits, higher than the rate for LSD or other hallucinogens. This rate was also stable from the prior year (Substance Abuse and Mental Health Services Administration 2007). Related drugs included ketamine, which accounted for 275 visits and dextromethorphan, which accounted for over 12,000 visits. Both ketamine and mega-dose dextromethorphan (5–10x recommended dose) can produce clinical symptoms similar to that of PCP.
In 1983, more than 66% of PCP-related deaths reported to the Drug Abuse Warning Network involved at least one other drug. Many of the PCP-related deaths were not the result of overdose or drug interaction or reaction, but the direct result of some external event facilitated by intoxication (e.g., homicides, accidents). The various manners of death (such as drowning and being shot by police) reported are consistent with the disorientation and violent aggressive behavior that can be stimulated by PCP (Crider 1986).

Etiology and Pathophysiology

Psychotomimetic Effects

The psychotomimetic effects of PCP result from its interaction with a unique high-affinity PCP receptor, demonstrated in 1979 (Zukin and Zukin 1979, Sircar et al. 1987), that selectively binds PCP-like drugs in rank order proportional to their behavioral potencies. By contrast, a wide variety of other drugs of abuse and neurotransmitters fail to bind to the PCP receptor at physiologically relevant concentrations (Zukin and Zukin 1979, Vincent et al. 1979, Sircar et al. 1987, Wong et al. 1988, Zukin et al. 1983). The PCP receptor is located within the ion channel gated by the N-methyl-d-aspartate (NMDA) receptor complex (Figure 59–1). When activated by binding of the major excitatory amino acid neurotransmitter of brain, l-glutamate, in the presence of the coagonist glycine, the cation channel gated by the NMDA receptor is activated, permitting influx of calcium ions. Binding of PCP-like drugs uncompetitively inhibits NMDA receptor activation by l-glutamate, thus disrupting NMDA receptor-mediated glutamatergic neurotransmission in a fashion that cannot be surmounted by increasing l-glutamate concentration. Such disruption of NMDA receptor function results in impairment of a number of mental functions including learning and memory (Handelman et al. 1987, Balster and Chait 1967, Thompson et al. 1987, Butelman 1989, Moerschbaecher and Thompson 1983). In animals, exposure to PCP-type drugs has been shown to result in reversible microscopic changes, including vacuolization, in specific populations of brain neurons (Olney et al. 1989). The applicability of these findings to humans remains to be established.

The effects of low-dose PCP administration have been extensively studied in volunteers. In normal subjects (Table 59–2), single intravenous doses of 0.05–0.1 mg/Kg caused withdrawal, negativism, and in some cases catatonic posturing; thinking processes became concrete, idiosyncratic, and bizarre in the absence of significant physical or neurological findings; and drug effects persisted for 4–6 hr (Bakker and Amini 1961, Luby et al. 1959, Ban et al. 1961, Davies and Beech 1960, Domino and Luby 1981, Rodin et al. 1959). In contrast to lysergic acid diethylamide (LSD) or amphetamine (Domino and Luby 1981, Cohen et al. 1961), PCP was noted to induce disturbances in symbolic thinking (Davies and Beech 1960, Cohen et al. 1961), perception (Luby et al. 1959, Rosenbaum et al. 1959), and attention (Domino and Luby 1981) strikingly similar to those observed in schizophrenia. Administration of PCP to schizophrenic subjects caused exacerbation of illness-specific symptoms persisting up to several weeks (Luby et al. 1959, Domino and Luby 1981), suggesting that schizophrenic or preschizophrenic individuals may be at significantly increased risk of behavioral effects from PCP abuse. At the doses used in these studies, which were equivalent to the typical 5-mg street dose (Burns and Lerner 1976), serum PCP concentrations of 0.01–0.1 μM are attained. At such levels, the PCP receptor is the only target site that would be significantly occupied by the drug (Figure 59–2).

Other Effects

Abusers often use PCP in higher or repeated doses leading to significantly higher serum concentrations than those associated selectively with psychotomimetic effects. In general, concentrations greater than 0.4 μM are associated with impairment of consciousness; at concentrations greater than 1.0 μM, coma, seizures, and respiratory arrest are common (Walberg et al. 1983, Pearce 1976). These neurological and metabolic effects result in part from interaction of PCP with sites other than the PCP-NMDA receptor, including catecholamine and indolamine reuptake sites (see Figure 59–2).

Pharmacokinetics

PCP is extremely lipid soluble. As a result, it can reach its brain target sites after oral, parenteral, smoked, inhaled (McCarron et al. 1981), or topical administration. Another consequence of its lipophility is its tendency to accumulate in lipid tissues throughout the body, including the brain (James and Schnoll 1976, Misra et al. 1979). Flashbacks may result from mobilization of adipose stores, for example, by exercise (James and Schnoll 1976, Misra et al. 1979).

---

Figure 59–1. Schematic model of NMDA receptor functioning. After magnesium blockade is relieved by membrane depolarization, the cation channel gated by the NMDA receptor can be activated by binding of l-glutamate and glycine. Binding of PCP within the channel blocks ion flux. There are a number of other regulatory sites external to the channel, of which two are illustrated: A site at which polyamines such as spermidine (SPD) positively modulate activation induced by l-glutamate (Glu) and glycine (Gly); and a site at which zinc and tricyclic antidepressants (AD) negatively modulate activation.
Because of its pKₐ of 8.5, PCP is largely ionized in the stomach or urinary tract. However, in the nonacidic environment of the small intestine, PCP becomes nonionized and is readily reabsorbed across the intestinal mucosa; subsequent enterohepatic recirculation may account for the fluctuating clinical course often observed.

Metabolism of PCP occurs primarily in the liver. Both PCP (Cook et al. 1982) and hydroxylated metabolites (Wong and Biemann 1976) are excreted in the urine. The serum half-life of PCP has been reported to vary from 4−72 hr (Cook et al. 1982, Done et al. 1977). Its volume of distribution is 6.2 L/kg (Cook et al. 1982).

PCP can be detected in urine for approximately 7 days following single administration and 2−4 weeks following chronic use. Metabolism of PCP appears to be unaffected by alcohol, although its entry into CNS may be increased (Godley et al. 1991). In contrast, THC appears to inhibit PCP metabolism, leading to higher serum levels and prolonged serum half-life (Godley et al. 1991).

**Tolerance and Dependence**

Tolerance to and dependence on PCP have not been formally investigated in humans. Clinical observations suggest that chronic PCP users are significantly less sensitive to a given dose than are casual users. In the case of ketamine, which shares the same fundamental mechanism of action as PCP, tolerance has been more formally observed in burn patients who require increased doses after a time to maintain the same level of analgesia (Carroll 1985). In laboratory animals, a twofold to fourfold shift to the right in the behavioral dose-response curve for PCP is observed in most studies, with indications that tolerance develops to a much greater extent with continuous administration (Balster 1986).

Signs of severe physical withdrawal have been noted in experimental animals when PCP is withdrawn after long-term administration (Balster 1986). In monkeys, even under circumstances in which physical withdrawal symptoms are minimal, normal behaviors are disrupted for a week or more after cessation of long-term PCP administration (Slifer et al. 1984). In humans, a single study indicated that one-third of 68 chronic PCP users had sought treatment to help them withdraw from PCP in the face of depressed mood, craving for the drug, and alterations in sleep and appetite that occurred when they attempted to cease drug use on their own (Tennant et al. 1981).

**Diagnosis and Differential Diagnosis**

**Phenomenology and Variations in Presentation**

Physicians must be alert to the wide spectrum of effects of PCP on multiple organ systems. Because fluctuations in serum levels may occur unpredictably, a patient being treated for apparently selective psychiatric or behavioral complications of PCP abuse may suddenly undergo radical alterations in medical status; emergency medical intervention may become necessary to avoid permanent organ damage or death. Any patient manifesting significant cardiovascular, respiratory, neurological, or metabolic derangement subsequent to PCP use should be evaluated and treated in a medical service; the psychiatrist plays a secondary role in diagnosis and treatment until physiological stability has been reached and sustained.

PCP-intoxicated patients may come to medical attention on the basis of alterations in mental status; bizarre or violent behavior; injuries sustained while intoxicated; or medical complications, such as rhabdomyolysis, hyperthermia, or seizures (Baldrige and Bessen 1990). As illicit ketamine use has increased significantly as part of the “club drug” phenomenon, it is important to remember that ketamine can induce the same spectrum of effects and complications, the chief difference from PCP being the much shorter duration of action of ketamine. In a series of 20 ketamine users presenting in Connecticut, the most frequent complications of ketamine abuse were severe agitation and rhabdomyolysis (Weiner et al. 2000).

**Psychiatric Presentation**

The presenting symptoms may be predominantly or exclusively psychiatric, without significant alterations in level of consciousness, and may closely resemble an acute schizophrenic decompensation (Luisada 1978) with...
Nonpsychiatric Findings in Phencyclidine patients) or status epilepticus (McCarron et al. 1981, Kessler et al. 1974). Seizures or neurological deficits have been reported, probably on the basis of focal cerebral vasocnstriction (Crosley and Binet 1979). Other motor signs have been observed, such as generalized rigidity, localized dystonias, facial grimacing, and athetosis (McCarron et al. 1981).

Nonpsychiatric Presentation

In PCP intoxication, the central nervous, cardiovascular, respiratory, and peripheral autonomic systems are affected to degrees ranging from mild to catastrophic (Table 59–3).

The level of consciousness may vary from full alertness to coma. Coma of variable duration may occur spontaneously or after an episode of bizarre or violent behavior (McCarron et al. 1981). Prolonged coma due to continued drug absorption from ruptured ingested packages of PCP has been described (Jackson 1989).

Nystagmus (which may be horizontal, vertical, or rotary) has been described in 57% of a series of 1,000 patients (McCarron et al. 1981). Consequences of PCP-induced central nervous system hyperexcitability may range from mildly increased deep tendon reflexes to grand mal seizures (observed in 31 of a series of 1,000 PCP-intoxicated patients) or status epilepticus (McCarron et al. 1981, Kessler et al. 1974). Seizures are usually generalized, but focal seizures or neurological deficits have been reported, probably on the basis of focal cerebral vasocnstriction (Crosley and Binet 1979). Other motor signs have been observed, such as generalized rigidity, localized dystonias, facial grimacing, and athetosis (McCarron et al. 1981).

Hypertension, one of the most frequent physical findings, was described in 57% of 1,000 patients evaluated, and it was found to be usually mild and self-limiting, but 4% had severe hypertension, and some remained hypertensive for days (McCarron et al. 1981). One fatal case of hypertensive crisis late in the course of PCP intoxication has been described (Eastman and Cohen 1975). Tachycardia occurs in 30% of patients. PCP-induced tachyphnea can progress to periodic breathing and respiratory arrest (Hurbut 1991). Autonomic signs seen in PCP intoxication may be cholinergic (diaphoresis, bronchospasm, miosis, salivation, bronchorrhea) or anticholinergic (mydriasis, urinary retention) (McCarron et al. 1981).

Hypothermia and hyperthermia have been observed (McCarron et al. 1981). Hyperthermia may reach malignant proportions (Thompson 1979).  

Rhabdomyolysis frequently results from a combination of PCP-induced muscle contractions and trauma occurring in relation to injuries sustained as a result of behavioral effects. Acute renal failure can result from myoglobinuria (Patel and Connor 1986). In children, PCP intoxication may result from ingestion of remnants of used PCP-impregnated cigarettes or from inhalation of sidestream smoke (Karp et al. 1980, Schwartz and Einhorn 1986, Welch and Correa 1980). Young children often present with impaired consciousness, ataxia, nystagmus, staring (Karp et al. 1980, Schwartz and Einhorn...
Assessment

Special Issues in Psychiatric Examination and History

The disruption of normal cognitive and memory function by PCP frequently renders patients unable to give an accurate history, including a history of having used PCP. Therefore, assay of urine or blood for drugs may be the only way to establish the diagnosis. PCP is frequently taken in forms in which it has been used to adulterate other drugs, such as marijuana and cocaine, often without the user's knowledge. One of the most alarming manifestations of this phenomenon is a preparation known variously as “illy,” “hydro,” “wet,” or “fry.” This mixture consists of a marijuana cigarette or blunt (sometimes tobacco) combined with embalming fluid (i.e., formaldehyde/formalin), but frequently also contains PCP, which may or may not be advertised to the user (Nelson 1999). “Fry” users are evidently aware that the combination may have extremely dangerous consequences, including impaired motor skills, incoherent behavior, paranoia, aggressive behaviors and long-term mental health problems (Peters et al. 2005), yet may not be fully aware of what is in the combination (Singer et al. 2005). Urine toxicological studies of individuals who use these mixtures frequently contain PCP, as well as other drugs (Singer et al. 2005). PCP precursors and synthesis by-products have been detected as well (Nelson 1999). In one recent study, use of frys was found in approximately 11% of substance abusing youths (Peters et al. 2003).

By disrupting sensory pathways, PCP frequently renders users hypersensitive to environmental stimuli to the extent that physical examination or psychiatric interview may cause severe agitation. If PCP intoxication is suspected, measures should be taken from the outset to minimize sensory input. The patient should be evaluated in a quiet, darkened room with the minimal necessary number of medical staff present. Assessments may need to be interrupted periodically.

Relevant Physical Examination and Laboratory Findings

Vital signs should be obtained immediately on presentation. Temperature, blood pressure, and respiratory rate are dose-dependently increased by PCP and may be of a magnitude requiring emergency medical treatment to avoid the potentially fatal complications of malignant hyperthermia, hypertensive crisis, and respiratory arrest. In all cases, monitoring of vital signs should continue at 2–4-hr intervals throughout treatment, because serum PCP levels may increase spontaneously as a result of mobilization of drug from lipid stores or enterohepatic recirculation.

Analgesic and behavioral changes induced by PCP not only predispose patients to physical injury but also mask these injuries, which may be found only with careful physical examination (Baldridge and Bessen 1990). On neurological examination, nystagmus and ataxia, although not conclusive, are strongly suggestive of PCP intoxication. Examination of deep tendon reflexes helps

Clinical Vignette 2

An 18-year-old high-school girl was transferred from the medical service to the psychiatric service 1 week after admission to the hospital. After friends had been unable to contact her for several days, the police were called and found the patient semiconscious on the floor of her apartment. While being transported to the hospital, the patient suddenly freed herself from restraints, assaulted one of the emergency medical personnel, and then lost consciousness. On presentation in the emergency department, blood pressure was noted to be 210/107 mm Hg, temperature was 104.1°F, and respiratory rate was 34/min. Extensive bruising was apparent on her back and lower extremities. While dehydration and electrolyte imbalances were being corrected, the patient had a grand mal seizure progressing to status epilepticus, which was treated with intravenous diazepam. Toxicological assays showed the presence of PCP in her urine; urinalysis was positive for heme.

She was admitted to the medical intensive care unit, where intensive measures to stabilize her condition were instituted. Vital and neurological signs fluctuated for the next 3 days as she slipped in and out of coma. On the fourth day, the patient regained consciousness but was delirious. She attempted to assault a nurse and was placed in four-point restraints. On transfer to the psychiatry service, temperature and blood pressure were within normal limits; deep tendon reflexes were mildly to moderately hyperactive. She was oriented to time and place, but cognitive functions were globally deficient. She refused neuroleptic medication. For the first 2 days on the service, she was mute. On the third day, she began stating repeatedly, “I was dead and I came back to life.” On several occasions, staff reported that she appeared to be responding to internal stimuli, but she denied it. On the fifth day, she was able to give a history. She stated that PCP was her drug of choice and that she had used it for several years on a weekly basis. Before admission, she had obtained a new supply, in liquid form, from a source she had not previously used. She had dipped approximately 10 cigarettes in the liquid and had smoked an unknown number of them in a period of several hours. She “got high” but then “died and knew I was dead.” She explained that she remembered suddenly falling to the floor and being unable to see, move, or hear for a long time. She recalled being aware of her condition and situation before being found but had no memory of events in the hospital until shortly before her transfer to the psychiatry service. She stated, “I’m a little crazy but that will clear up in another few days; it always has before. Dust [PCP] does that to a person.” Mental status examination now revealed significant improvement in cognitive functioning. On the seventh day, she signed out against medical advice. During the discharge interview, she continued to maintain that she had literally died and come back to life. Three weeks after discharge, she was admitted to another hospital for treatment of PCP intoxication.

Comment

This clinical vignette illustrates the emergence of a purely psychotic picture after resolution of catastrophic medical complications of high-dose PCP intoxication. It also illustrates PCP dependence in a chronic user.
to establish the degree of nervous system hyperexcitability. Crossed or clonic deep tendon reflexes alert the physician to the possibility of subsequent seizures.

Because PCP is usually supplied in combination with other drugs and is often misrepresented, toxicological analysis of urine or blood is essential. However, there may be circumstances in which PCP may not be detected in urine even if it is present in the body, for example, when the urine is alkaline. On the other hand, in chronic PCP users, drug may be detected in urine up to 30 days after last use (Simpson et al. 1982). It must be kept in mind that false-positive PCP results can be caused by the presence of venlafaxine and O-desmethylvenlafaxine (Sena et al. 2002), or dextromethorphan (Shier et al. 2000). Urine should be tested for heme because of the possible complication of myoglobinuria.

Blood and urine samples should be sent for toxicological analysis. In addition, serum uric acid, creatine kinase, aspartate transaminase, and alanine transaminase elevations, common findings in PCP intoxication, were found to be associated with rhabdomyolysis in 22 of 1,000 cases (McCarron et al. 1981).

### Differential Diagnosis

The presence of nystagmus and hypertension with mental status changes should raise the possibility of PCP intoxication. Because of the close resemblance of both the acute and the prolonged forms of PCP psychosis to schizophrenia, and the increased sensitivity of patients with schizophrenia to the psychotomimetic effects of the drug, an underlying schizophrenia spectrum disorder should be considered, particularly if paranoia or thought disorder persists beyond 4–6 weeks after last use of PCP. PCP psychosis may also resemble mania or other mood disorders. Therefore, in all cases, a detailed psychiatric history should be obtained. Robust response of psychotic symptoms to treatments with neuroleptics would favor a diagnosis other than simple PCP psychosis.

PCP psychosis is readily distinguishable from LSD psychosis in normal as well as in individuals with schizophrenia by the lack of typical LSD effects, such as synesthesia. The cluster of psychotic symptoms, hypertension, and stereotypy may be seen in both PCP psychosis and chronic amphetamine psychosis; in such cases, accurate histories and toxicological analysis are particularly important.

In cases involving prominent PCP-induced neurological, cardiovascular, or metabolic derangement, encephalitis, head injury, postictal state, and primary metabolic disorders must be ruled out (Lerner and Burns 1978). Either intoxication with or withdrawal from sedative-hypnotics may be associated with nystagmus (Baldrige and Bessen 1990). Neuroleptic malignant syndrome should be ruled out in the differential diagnosis of PCP-induced hyperthermia and muscle rigidity (Baldrige and Bessen 1990).

### Course and Natural History

As drug levels decline, the clinical picture recedes in 5–21 days through periods of moderating neurological, autonomic, and metabolic impairments to a stage at which only psychiatric impairments are apparent. Once the physical symptoms and signs have cleared, the period of simple PCP psychosis may last 1 day to 6 weeks, whether or not neuroleptics are administered, during which the psychiatric symptoms and signs abate gradually and progressively. Even after complete recovery, flashbacks may occur if PCP sequestered in lipid stores is mobilized. Any underlying psychiatric disorders can be detected and evaluated only after complete resolution of the drug-induced psychosis. Although systematic studies in humans have not been carried out, clinical experience predicts a high likelihood of resumption of PCP use after recovery from PCP psychosis.

### Overall Goals of Treatment

The hierarchy of treatment goals begins with detection and treatment of physical manifestations of PCP intoxication. Equally important are measures to anticipate PCP-induced impulsive, violent behaviors and provide appropriate protection for the patient and others. The patient must then be closely observed during the period of PCP-induced psychosis, which may persist for weeks after resolution of physical symptoms and signs. Finally, the possibly dramatic medical and psychiatric presentation and its resolution must not divert the attention of the psychiatrist from full assessment and treatment of the patient's drug-seeking behavior.

### Standard Approach to Treatment

#### Physician-Patient Relationship in Psychiatric Management

In contrast to psychotic states induced by drugs such as LSD, in which “talking the patient down” (by actively distracting the patient from his LSD-induced sensory distortions and convincing the patient that his or her distress stems from nothing more than the temporary effects of a drug that soon will wear off) may be highly effective, no such effort should be made in the case of PCP psychosis, particularly during the period of acute intoxication, because of the risk of sensory overload that can lead to dramatically increased agitation. The risk of sudden and unpredictable impulsive, violent behavior can also be increased by sensory stimulation.

#### Somatic Treatments

There is no pharmacological competitive antagonist for PCP, in contrast to opiates and benzodiazepines. Any compound competing with PCP for binding to its recognition site within the NMDA receptor–gated ion channel would also block the channel and prevent ion flux, thus exerting PCP-like effects. Oral or intramuscular benzodiazepines are recommended for agitation. The degree to which PCP induced behavioral symptoms respond to antipsychotics remains controversial. Higher potency neuroleptics (e.g., haloperidol, pimozide) have been found to be superior to lower potency agents (e.g., chlorpromazine) (Giannini et al. 1984) and may also be effective against ketamine-induced psychosis (Giannini et al. 2000). Further low potency neuroleptics such as chlorpromazine may be more likely to decrease seizure threshold. However, such agents may also act as effective alpha-blocking agents, and may assist in the management of hypertension. Ascorbic acid has been reported to significantly augment the therapeutic effects of haloperidol (Giannini et al. 1987). Because of rela-
tively low rates of PCP induced psychosis, relatively little clinical literature is available concerning efficacy of atypical antipsychotics, relative to older high potency agents. Nevertheless, atypical antipsychotics, especially clozapine, have proven highly effective in animal models against both acute (Dunn et al. 2007, Geyer and Ellenbroek 2003, Linn et al. 2003.) and sustained (Abdul-Monim et al. 2006, Elsworth et al. 2007, Didriksen et al. 2007, Amati et al. 2007, Dunn and Killcross 2006, Hashimoto et al. 2005) effects of phencyclidine administration.

In addition to antipsychotics, other classes of agent have been investigated. Meperidine was shown to be effective in one study (Giannini et al. 1985), although its use has not achieved widespread popularity. Benzodiazepines or other sedative hypnotic are frequently employed for the management of agitation or excitation during acute PCP intoxication (Leikin et al. 1989), and have proven useful also in experimentally induced ketamine psychosis (Krystal et al. 1985). The antiepileptic drug lamotrigine has also proven effective against ketamine-induced psychosis (Anand et al. 2000), although clinical data are lacking. Diphenhydramine has been reported to be effective in the management of PCP-induced dystonias but not generalized rigidity (Leikin et al. 1989).

Because PCP is frequently taken in combination with other drugs, a toxicological analysis of urine and/or blood for other drugs besides PCP is essential. Urine should also be tested for heme because of the potential complication of myoglobinuria. Serum uric acid, CPK and SGOT/SGPT elevations may also be associated with PCP-induced rhabdomyolysis.

Because of the large volume of distribution of PCP, dialysis is ineffective as a means of clearing the drug from circulation. Gastric lavage using activated charcoal may be effective in binding PCP and increasing its nonrenal clearance (Picchioni and Conroe 1979, Jones et al. 1987). Cathartics, such as sorbitol or magnesium citrate, may also increase transit time and thus decrease intestinal absorption. Because PCP is a weak base, urinary acidification is frequently recommended. Decreasing urinary pH from 7–5 and forcing diuresis may increase PCP clearance 10-fold. However, since 90% of PCP is metabolized by the liver, and only 10% is excreted unchanged in urine, the benefits of the increased renal clearance may not outweigh the risks (Tong et al. 1975). Further, because of the possibility of electrolyte imbalance and additional nephrotoxic effects, this should be considered a measure of last resort.

Recent drug development activities may produce more specific and effective pharmacotherapy of PCP-induced abnormalities. Large doses of oral glycine, which recently have been used safely and effectively in treatment of negative symptoms of schizophrenia in research studies in humans (Javitt 2006, Javitt et al. 2004), have been shown to reverse PCP-induced dopaminergic dysregulation in rodents (Toth and Lajtha 1986). Similar effects are seen with agents, such as the naturally occurring compound sarcosine, that increase glycine levels by blocking brain glycine transporters (Javitt 2006, Javitt et al. 2004, Toth and Lajtha 1986). Increased glycine concentrations at the NMDA receptor would increase channel activation and promote diffusion of PCP molecules from their binding sites within the channel. A single dose of a monoclonal anti-PCP IgG antibody has been found to produce profound reduction of the effects of daily PCP doses for two weeks or longer in rats (Hardin 2002). Hopefully such strategies will be tested and validated in humans.

Special Features Influencing Treatment

Psychiatric Comorbidity

PCP psychosis may be clinically indistinguishable from schizophrenia (Luby et al. 1959, Luisada 1978) or mania (Slavney et al. 1977). It has been suggested that some patients who remain psychotic for weeks after PCP ingestion may have an underlying predisposition to schizophrenia or mania. In some series, significant percentages of patients suffering prolonged PCP-induced psychosis are subsequently hospitalized with non-drug-induced schizophrenic disorders (Luisada 1978). In the case of a patient with schizophrenia, responsiveness to neuroleptic treatment may resume after recovery from prolonged PCP psychosis.

General Medical Comorbidity

Patients with preexisting neurological, cardiovascular, respiratory, or renal disorders are at increased risk for complications of PCP intoxication, such as seizures, stroke, hypertensive crisis, respiratory arrest, or renal failure. Abusers of more than one drug may be at increased risk from the presence of other drugs exerting toxic effects on the same organ systems (e.g., cardiovascular effects of cocaine and amphetamine) or because of damage to specific organs secondary to infectious complications of parenteral drug use.

References

Introduction
Hallucinogenic agents have been used by humans for thousands of years. These agents, which derive from a variety of natural and synthetic sources, share the property of inducing a wide range of effects on perception, cognition, and affect in the absence of a delirium. They can induce depersonalization and derealization, and their use can result in intermittent or persistent recurrent perceptual alterations. Tolerance may develop with repeated use, but classical withdrawal symptoms usually do not occur. Many hallucinogens exist: they have essential general features but are different in the specific effects, use or abuse patterns, and propensity to induce psychosis.

The definition of an hallucinogenic drug has been a matter of controversy (Hollister 1968, Jarvik 1970, Brawley and Duffield 1972, LaBarre 1975, Martin and Sloan 1977, Grinspoon and Bakalar 1979, Schultes and Hofmann 1980). More than 90 species of hallucinogenic plants afford an ethnobotanical definition. Hundreds of substituted phenylethylamines and tryptamines lend themselves to chemical characterization. Because few have been systematically studied in humans, hallucinogens have been defined by their botanical or chemical rubrics rather than their psychophysiological effects. To address the problem of classification, one may define as hallucinogenic “any agent which has alterations in perception, cognition, or mood as its primary psychobiological action in the presence of an otherwise clear sensorium. Most commonly this includes indolealkylamines and phenethylamines, and excludes, inter alia, the anticholinergics, the arylcyclohexalamine dissociative anesthetics such as phencyclidine, stimulants such as amphetamine and cocaine, bromism and heavy metal intoxication” (Abraham et al. 1996). Instruments are now available which objectify the human factor in hallucinogenic responses (Hermle et al. 1994, Strassman et al. 1994). Future definitions may likely be refined based on neuroreceptor and second messenger drug effects.

Ethnobotanical Hallucinogens
Human ingestion of hallucinogens can be traced back thousands of years. In the Americas, Europe, and Africa, hallucinogens were used for consecration during religious ceremonies, for divination, and as a tool for rites of passage and shamanic healing. It is possible that the soma of the 3500-year-old Hindu-Aryan Rig Veda (Smith 2000), the kykeon of the ancient Greek rites of the Eleusinian Mysteries (Wasson 1961) and the manna of the Judeo-Christian Old Testament (Merkur 2000) may have all been hallucinogen-containing substances.

The majority of these botanicals grow in the Americas. In South and North America, cacti containing the
hallucinogen mescaline are still widely used by a number of Native peoples. In South America, boiled potions are made from *Trichocereus* species, a cactus containing about 1% mescaline. A much more potent mescaline-containing cactus, peyote (*Lophophora williamsii*), grows naturally in Northern Mexico and along the Texas–Mexico border. The Huichol of Mexico has used peyote as a religious sacrament continuously for 3000 years (Schafer and Fursth 1998), as have the Native American Church (NAC) of the United States (USA) and Canada. In the NAC, peyote is treasured as a holy sacrament from God to be ingested in all-night prayer ceremonies. Currently, the NAC has as many as 300,000 members and the ceremonial use of peyote is permitted by federal law (American Indian Religious Freedom Act of 1978 and successive Amendment of 1994). Several reports in the medical literature allude to participation in NAC meetings as a successful, culturally sensitive therapy for alcoholism and other drug addictions among Native Americans (Bergman 1971, Albaugh and Anderson 1974, Garrity 2000). In a study assessing neurocognitive performance and psychological well-being of 176 Native Americans, long-term peyote use was not associated with any degradation in neurocognition and, in fact, was associated with better mental health than nonusers (Halpern et al. 2005).

Hallucinogenic mushrooms containing psilocybin (4-phosphoryloxy-N,N-dimethyltryptamine) and psilocin (4-hydroxy-N,N-dimethyltryptamine), especially from the genus *Psilocybe*, are found throughout the Americas, Europe, and Asia. *P. cubensis* typically contains 1.6 mg psilocybin per gram of dried mushroom; a dose of 40 μg/kg induces a 3- to 4-h intoxication. The ancient cultures of Meso-America almost certainly venerated the *Psilocybe* experience (Wasson 1961), and some Native Americans of Oaxaca, Mexico continue to use these mushrooms in religious ceremonies to this day. Easily grown and indigenous to many parts of the USA (Halpern 2004), *Psilocybe* mushrooms are commonly trafficked as hallucinogens on the illicit market. Psilocybin can, in a carefully controlled research setting, reliably induce “deeply mystical” states (Griffiths et al. 2006), and has been postulated as offering important medical treatments for cancer-related anxiety (see www.canceranxietystudy.com), treatment-resistant obsessive-compulsive disorder (Moreno et al. 2006), and for cluster headache (Sewell et al. 2006).

Dimethyltryptamine (DMT), a short-acting hallucinogen, is also present in a wide variety of botanicals. Many indigenous peoples of the Amazon and elsewhere ingest potent DMT snuffs prepared from seeds of *Anadenanthera peregirina*, *A. columbrina*, and other botanicals (Schultes and Hofmann 1992). Originating in Brazil, two religions using an orally active form of DMT have evolved out of traditional practices and Christian beliefs in the 20th century, and are legally recognized in Brazil, Peru, Columbia, and the Netherlands. In 2006, the United States Supreme Court in a landmark unanimous decision (Gonzales v. UDV 2006) recognized that Americans also are afforded protection from religious persecution and legal sanction for membership in an ayahuasca-using religion. These religions, the União do Vegetal (UDV) and the Santo Daime, prepare a “tea” (ayahuasca, hoasca, daime) containing DMT from the leaves of *Psychotria viridis*, together with reversible monoamine oxidase inhibitors (MAOIs) derived from the vine *Banisteriopsis caapi*. Without inactivation of monoamine oxidase, DMT is not orally active. About 1–2 mg/kg of DMT, in the presence of sufficient MAOI, is a typical psychoactive dose. Subjective effects last 3–4 h and are frequently described as joyful and serene (Barbosa et al. 2005). Members of the ayahuasca-using religions often claim that it helps in treating drug addiction and “inoculating” teenage members from engaging in drug abuse (Doering-Silveira et al. 2005). Many strains of reed-canary grass (*Phalaris sp.*) found throughout North America contain appreciable amounts of DMT (Baxter and Slaytor 1972), but have apparently not been used by traditional societies.

One ceremonial drug that is no longer used traditionally is lysergic acid amide, a natural analog of lysergic acid diethylamide (LSD). This nonethylated amide was consumed by the ancient Aztecs in a drink called *Ollinuaqui*, prepared from the seeds of the Tlilitzin plant (*Turbinia corymbosa*). Lysergic acid amide is also found in the seeds of the morning glory (*Ipomoea violacea*). In recent times, some individuals have attempted to use morning glory seeds for recreational intoxication, although other alkaloids in these seeds induce nausea and headache, and commercially obtained seeds are often coated with emetic chemicals or captan, a purple-colored fungicide and carcinogen that induces emesis, or with other emetic chemicals so as to discourage illicit consumption.

Less common natural hallucinogens include 5-methoxy-DMT, bufotenine (5-hydroxy-DMT), and salvinorin-A. Bufotenine and 5-methoxy-DMT can both be extracted from the venom of the American toad, *Bufo alvarius*, and then smoked for a powerful 15-min intoxication (Weil and Davis 1994). “Toad licking” or actual ingestion of the skin of the *Bufo alvarius* is poisonous. Salvinorin-A, a trans-neoclerodane diterpenoid, produces a 15–25 min intoxication when 200–500 μg are smoked. Unlike other hallucinogens, salvinorin A acts as a potent and selective κ-opioid receptor agonist without any action at 5-HT₂A serotonin receptors, the molecular target thought to mediate the actions of the more commonly used and better known hallucinogens (Roth et al. 2002). It is extracted from the *Salvia divinorum* plant, and has been used as a religious sacrament by Mazatec shamans in Mexico for hundreds of years (Valdes 1994, Vortherms and Roth 2006). Recently, it has been used as a recreational drug in America and elsewhere, largely through promotion on the Internet (Halpern and Sewell 2005).

One of the few Old World botanical hallucinogens still used for religious purposes is *Tabernanthe iboga*, a shrub that contains up to 6% of the indole alkaloid, ibogaine. In Western Africa, the Bwiti Cult and certain hunter-gatherer peoples of Gabon and the Congo continue to use a root-bark preparation from this plant (Fernandez and Fernandez 2001). Ibogaine induces intoxication for 6 h or more; the compound has been patented in the USA as a potential treatment for addiction.

In short, many hallucinogens are classical examples of drugs discovered by traditional societies and subsequently adopted for both licit and illicit use in industrialized countries. Unlike many other ethnobotanicals, however, hallucinogens continue to be widely used in their original religious settings, even as they are simultaneously used and abused in modern societies.
Synthetic Hallucinogens

The dawn of modernity for hallucinogenic drugs can be placed to the moment in 1943 when Albert Hofmann, a Swiss chemist, discovered the potent psychological effects of LSD. Three days after an accidental exposure, Dr. Hofmann intentionally ingested 250 μg of LSD on April 19, 1943 and soon traveled home via bicycle as the pronounced psychological effects commenced. Within a decade, the drug was being tested as an agent of chemical warfare in the USA and Europe. Within 2 decades it assumed cult status among the ministry, academics, and students, culminating in an epidemic of abuse in its third decade—the late 1960s. Congress responded with the Drug Abuse Control Amendments of 1965 and 1968, which choked off drug supplies to researchers, and criminalized drug sale and use. The scientific impact of these laws was to retard the advance of knowledge in this field for a generation.

The development and chemical identification of additional agents causing LSD-like mental symptoms, however, proceeded apace. This work has both clarified aspects of their mechanisms of action and created a challenge to defining hallucinogens. Two classes of drugs appear to have commonalities with LSD. These include other substituted indolealkylamines (psilocybin, psilocin, ibogaine, DMT, and bufotenine, inter alia) and the phenethylamines (mescaline, 3,4-methylenedioxymethamphetamine [MDMA], methylenedioxymphetamine [MDA], 4-brom-2,5-dimethoxyphenethylamine [2CB], and 2,5-dimethoxy-4-methamphetamine [DOM], inter alia) (Figure 60–1). The chemist Alexander Shulgin has synthesized and tested at least 179 phenethylamines (Shulgin and Shulgin 1991) and 55 indolealkylamines (Shulgin and Shulgin 1997) for hallucinogenic properties.

Human Experimentation with Hallucinogens

Abraham (2000) described a biphasic curve regarding enthusiasm and caution in publications on the hallucinogen, LSD, in the medical literature from 1960 to 1994 (Figure 60–2). Early in its history LSD spawned a flurry of positive reports regarding its clinical benefits, but following an epidemic of abuse, adverse reports predominated. Regulatory suppression of LSD research in the US then followed for several decades.

Recently, however, this unique class of drugs has inspired a new wave of research with selected hallucinogens with regulatory oversight of the issues of safety and efficacy. Studies have examined the safety of peyote in religious use (Halpern et al. 2005); the psychological effects of psilocybin, and dimethyltryptamine (Gouzoulis-Mayfrank et al. 2005); and possible therapeutic uses, such as ongoing studies for refractory anxiety in cancer patients and posttraumatic stress disorder (PTSD).

Hallucinogens have been used as experimental psychoses ("psychotomimetics"). A Swiss team has found increased metabolic activity in the frontal cortex of subjects on the dissociative anesthetic ketamine (Vollenweider et al. 1997), and in subjects during an experimental psychosis from psilocybin, increased serotonin-2 agonist activity (Vollenweider et al. 1998). Evidence is also emerging which supports the experimental use of hallucinogens for the treatment of psychiatric disorders. In a randomized trial of ketamine for depression, Zarate et al. found that the drug had benefits for a week following a single dose (Zarate et al. 2006).

MDMA (Ecstasy)

3,4-Methylenedioxymethamphetamine (MDMA, commonly known as "ecstasy") is a synthetic amphetamine analog that is also similar to mescaline. It was originally synthesized by Dr. E. Merck in 1912 and patented in Germany in 1914 (Merck 1914, Freudennann et al. 2006). It was never marketed and did not attract attention until the 1970s when it was described as an hallucinogen analog (Hardman et al. 1973). (This pre-clinical study (Hardman et al. 1973) was conducted in the early 1950s as part of the U.S. government’s research into compounds for interrogation and warfare but wasn’t declassified until 1973.) Anecdotal reports (Gaston and Rasmussen 1972, Shulgin and Shulgin 1991) suggest that a tiny minority may have used MDMA in the late 1960s, but the first verified illicit use of MDMA began in the 1970s or early 1980s. Recreational use of MDMA
took root due to its psychological effects and the fact that it was available legally, and was partially fueled by reports of the use of MDMA as a psychotherapeutic adjunct (Shulgin and Nichols 1978). In 1985, in response to the expanding recreational spread of MDMA in the dance club and “Rave” scene, the Drug Enforcement Administration (DEA) started the procedures to place MDMA into Schedule I. When evidence emerged that a structurally related congener, 3,4-methylenedioxyamphetamine (MDA) damages serotonergic neurons in rodents (Ricaurte et al. 1985), the DEA used this report to justify emergency Scheduling (Lawn 1986). Therapists who had used MDMA to assist psychotherapy challenged this placement before an Administrative Law Judge of the DEA who agreed with these petitioners and recommended MDMA be placed into Schedule III. This recommendation was not accepted by the DEA Administrator and MDMA in the United States has remained in Schedule I. MDMA may indeed induce 5-HT depletion (which may or may not reflect neurotoxicity) which may be associated with behavioral changes (Baumann et al. 2007). The actions of the DEA were supported by subsequent early reports that MDMA is toxic to animal (Stone et al. 1986, O’Hearn et al. 1988, Fischer et al. 1995, Hatzidimitriou et al. 1999) and possibly human brain (McCann et al. 1998—a study which has since been retracted, but found by others Semple et al. 1999, Reneman et al. 2002a, 2002b). High or frequently repeated doses of MDMA may be harmful to the brain. Heavy ecstasy users exhibit subtle but detectable impairments in memory and executive function, though the clinical significance of these findings remains unclear.

The publicity that followed the scheduling of MDMA only served to increase its popularity, particularly on college campuses (Peroutka 1987). Recognition of this trend led the National Institute of Drug Abuse (NIDA) and the Substance Abuse Mental Health Services Administration (SAMHSA) to begin formal collection of epidemiologic data in the mid to late 1980s. In the intervening years, the pattern of MDMA use has changed with use peaking among American teens in 2001. These factors have heightened public awareness of the drug through the years of reported increased use that has since leveled off in the later 2000s.

**Hallucinogen Intoxication**

**Diagnosis**

**Definition and Diagnostic Features**

**DSM-IV-TR Criteria**

**Hallucinogen Intoxication**

A. Recent use of hallucinogen

B. Clinically significant maladaptive behavior or psychological changes (e.g., marked anxiety or depression, ideas of reference, fear of losing one’s mind, paranoid ideation, impaired judgment, or...
impaired social or occupational function) that developed during or shortly after, hallucinogen use.

C. Perceptual changes occurring in a state of full wakefulness and alertness (e.g., subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, synesthesias) that developed during, or shortly after, hallucinogen use.

D. Two (or more) of the following signs, developing during, or shortly after, hallucinogen use:

1. Pupillary dilatation
2. Tachycardia
3. Sweating
4. Palpitations
5. Blurring vision
6. Tremors
7. Incoordination

E. The symptoms are not due to a general medical condition or are not better accounted for by another mental disorder.

Assessment and Differential Diagnosis

Chemical identification of hallucinogens in emergency specimens with methods such as gas chromatography-mass spectrometry remains costly and time consuming. Thus, clinicians in emergency settings must rely on a careful drug history, the social context of possible drug use, the information from the less drug-affected friends of the patient, the mental status examination, and signs apparent from the physical examination. The high potency of chemically pure LSD permits its distribution in single drops of solution. Thus, blotter paper (often marked with stamps of cartoon characters or New Age symbols) or a single sugar cube can easily carry more than the 50–100 μg of LSD necessary for the user to “trip” 6–12 h. Routes of administration other than by ingestion are rare. Autonomic arousal is the rule, with tachycardia, increased deep tendon reflexes, and dilated pupils present regardless of whether euphoria or panic is present. Hypersensitivity to visual and auditory stimuli is common, with atypical affective responses as the result.

Motor function is reduced, so patients seeking assistance in the emergency room are not likely to act out aggressively. “Bad trips” are drug-induced panic attacks in the context of an hallucinogenic experience, associated with feelings of unreality, confusion, and the flooding of the senses with unbidden imagery. Acute presentations of the proverbial “bad trip” have declined in conjunction with a decline in use in the last decade (SAMHSA’s Drug Awareness Warning Network, DAWN; www.dawninfo.samhsa.gov, Substance Abuse Mental Health Services Administration, 2006). Reasons for the relative rarity of emergency room visits may be a reflection of increased awareness of safer procedures for managing the intoxication (many users report having a non-drug using “sitter” with extensive prior experience with hallucinogens) and the average dose of LSD sold on the street has decreased from 250 μg per perforated square of blotter paper in the late 1960s to 100–50 μg or less today, which may be a more “manageable” dosage for the inexperienced user to navigate when experiencing a profoundly dysphoric “bad trip.”

Differential Diagnosis

The differential diagnosis of an acute hallucinogenic intoxication includes intoxication by other agents (such as phencyclidine [PCP], cocaine, amphetamines, anticholinergics, and inhalants, among others). It also includes acute schizophrenia or affective disorder, panic disorder, head injury, sedative, hypnotic, anxiolytic, or alcohol withdrawal (including gamma-hydroxybutyrate [GHB]), metabolic disorders such as hypoglycemia and hyperthyroidism, seizure disorder, acute vascular events, release hallucinations of ophthalmologic disease, and the complications of central nervous system (CNS) tumors. Age, along with prior clinical history, the history of the current event, physical examination, and toxicology screen for suspected nonhallucinogenic agents usually reveal the diagnosis.

A patient presenting with a history of taking LSD may still, in fact, have ingested a different substance. The street practice of adulteration or mislabeling of the drug is common, though some 80% of street samples have been found to correctly contain LSD (Abraham 1983a). Psychosis following a smoked agent suggests PCP. Differentiating between PCP and LSD is clinically important, since LSD-induced panic responds well to oral benzodiazepines, while PCP delirium requires high potency antipsychotic medications such as haloperidol. A “palm test” can be employed to differentiate PCP from LSD toxicity (Abraham and Aldridge 1993). This is performed by the examiner holding an open palm in front of the patient, and asking “the names of all the colors you see in my palm.” The LSD patient often ticks off a series of vivid colors and occasional images. The dissociated, aggresive PCP patient attempts to attack the hand.

Epidemiology

Among hallucinogens, LSD remains the most popular in its class among American high school students. An annual drug survey of 45,000 students by the Monitoring the Future Program of the University of Michigan has been performed since 1975. There is a downward long-term trend of LSD lifetime use among American secondary school students. In 2001, 10.9% of seniors reported using LSD at least once. By 2006 that figure had fallen to 3.3%. Attitudes among seniors have relaxed regarding their perception of dangers from LSD use. In 1990, 44.7% of the students believed users were harming themselves from the drug if taken once or twice but by 2006 only some 36.1% held this view. Risk of harm from regular use of LSD was believed by 84.5% of seniors in 1990 and has similarly trended downward with 69.3% expressing this view in 2006. Disapproval of any use has remained fairly constant over the years with 88% of seniors disapproving of one or two uses of LSD and 99.5% disapproving of regular LSD use in 2006. While nearly half
of the seniors in 2000 (46.9%) reported that LSD is “fairly easy” or “very easy” to get, availability has trended downward to 29% in 2006 (Johnston et al. 2006). The price for a single dose of LSD has held fairly constant: DEA reports it retails for $2 to $5 in 2006 (Office of Diversion Control, 2006). Other hallucinogens are not well studied.

Comorbidity Patterns
Individuals with antisocial personality disorder are more likely to have comorbid drug use including hallucinogens (Compton et al. 2005). The obverse is also true, that is, subjects with drug abuse are more likely to have antisocial personality disorder (Compton et al. 2000).

Course
Acute intoxication with LSD generally lasts 6–12 h.

Etiology and Pathophysiology

Genetic Factors
There are no known genetic factors in hallucinogen abuse.

Neurobiological Factors
The acute effects of “tripping” on LSD-like (i.e., with similar psychic effects, e.g., psilocybin or mescaline) hallucinogens are variable and profound. Classic descriptions are offered by Albert Hofmann (1980) and Aldous Huxley (1954). Subjects given LSD without their knowledge suffer more anxiety, hypomotility, and speech disruption than those who take it knowingly. LSD is active within 30 min of ingestion of a 50–100 μg dose. Physically, the drug’s autonomic arousal is associated with mydriasis which lasts for much of the trip. The flood of rapidly changing perceptual, affective, and cognitive effects is by alternate turns exhilarating, nerve wracking, and incapacitating. Table 60–1 illustrates a typical time course for the psychiatric effects of LSD.

The effective hallucinogenic dose varies widely between drugs in this class, and between individuals. Thus, a dose of 1 μg/kg of LSD is approximately equivalent to 150–200 μg/kg of psilocybin and 5–6 mg/kg of mescaline (Hollister 1984). Adverse reactions have been observed following 40 μg of LSD in some individuals, but absent in others taking as much as 2000 μg. The conventional explanation for this variability of response is instructional set, anticipation of drug effects due to previous experience, and environmental setting affect outcome (Zinberg 1984). Additionally, personality, preexisting mental illness, and genetic vulnerability to mental illness are also likely to be important.

Unlike the chronic use of stimulants, like amphetamine and cocaine, chronic use of hallucinogens does not lead to physiological dependence with only minor exceptions (Stone et al. 2006). On the other hand, tolerance to LSD rapidly builds in 4–7 days, and lasts 3 days (Abramson et al. 1956). LSD shows cross-tolerance with psilocybin, dimethyltryptamine, and mescaline, but not with amphetamines, or cannabis (Rosenberg et al. 1964). There is no withdrawal or documented fatalities from overdose. Homicide and suicide in the acute drug state have been reported (Cohen 1960, Reich and Hepps 1972) but are rare, ostensibly because of drug-induced hypomotility. The mechanism of action of hallucinogens is complex. Titeler et al. (1988) have shown that hallucinogenic potency of LSD and selected phenylisopropylamines correlates with the drug’s ability to bind to the postsynaptic 5-HT2A receptor (Titeler et al. 1984, Nichols 2004) (see Figure 60–3).

Neurophysiologic studies in animals support the involvement of postsynaptic 5-HT2A for hallucinogenic activity (Abraham et al. 2002, Nichols 2004). Hallucinogens simultaneously decrease spontaneous activity in the locus coeruleus, considered a novelty detector in the midbrain, while enhancing sensory responses of the locus coeruleus by activating N-methyl-D-aspartate receptors. In the cerebral cortex, the drugs both inhibit and induce activity by exciting GABAergic and glutamatergic neurons respectively (see Figure 60–4). Stimulation of 5-HT2A by hallucinogenic compounds specifically activates the pertussis toxin-sensitive Goi/o protein and Src kinases in cortical pathways. Interestingly, activation of 5-HT2A receptors by nonhallucinogenic compounds (e.g., lisuride) does not activate these proteins (González-Maeso et al. 2007). Hallucinogenic effects can be modeled when 5-HT2A are expressed only in the cortex, implying subcortical involvement is not needed for hallucinogenic actions (González-Maeso et al. 2007).

The presence of selective serotonin reuptake inhibitors blunts hallucinogenic effects, possibly through the activation of 5-HT1 receptors (Aghajanian and Marek 1999, Bonson et al. 1996). GABA, anxiolytic agents (e.g., benzodiazepines) promptly bring the dysphoria of a “bad trip” to an end, presumably by inhibition of the locus coeruleus.

Several European groups have published neuroimaging studies of the acute effects of hallucinogens (Hermle et al. 1994, Vollenweider et al. 1997). Hermle and colleagues using single photon emission computed tomography (SPECT) in healthy volunteers found that mescaline resulted in increased metabolic activity in the temporofrontal cortex, in distinction to patients with schizophrenia, who show hypofrontality. Vollenweider and colleagues administered psilocybin to healthy volunteers who were then studied with 18F-deoxyglucose positron emission tomography (PET). This hallucinogen globally increased brain cingulate, frontal and medial temporal

Figure 60–3  Affinity and potency of selected phenylisopropylamine hallucinogens and LSD at the 5-HT$_2$ receptor. The 5-HT$_2$ receptors in rat frontal cortex were labeled with $^3$H-DOB (4-bromo-2,5-dimethoxyphenylisopropylamine). Sixteen phenylisopropylamine compounds and LSD were then assayed for affinity at these sites. Subjective human potencies were determined by Shulgin. Spearman’s ranked correlation coefficient between 5-HT$_2$ affinities and hallucinogenic potencies is 0.09. A correlation between affinities and drug discrimination potencies in rats (data not shown) was 0.90 as well (Source: Reprinted with permission from Titeler M, Lyon RA, and Glennon RA (1988) Radioligand binding evidence implicates the brain 5-HT$_2$ receptor as a site of action for LSD and phenylisopropylamine hallucinogens. Psychopharmacology 94, 213–216.)

Figure 60–4  Schematic diagram of putative electrophysiological mechanism of action of hallucinogenic drugs. Depicted are serotonergic hallucinogenic inputs at the raphé nuclei and locus coeruleus, projecting to the vicinity of apical dendrites of layer V pyramidal cells in the neocortex. Hallucinogens, acting as partial agonists at 5-HT$_{2A}$ receptors, induce the release of glutamate from excitatory nerve terminals. Also shown are inhibitory modulators of 5-HT$_{2A}$-induced glutamate release: GABA, μ opiate, group II and III metabotropic glutamate, and possibly 5-HT$_{1B}$ receptors. NE, noradrenergic input; α1, alpha-1 adrenergic receptor; mGluR II/III, group II and III metabotropic glutamate receptor; GABA, γ-aminobutyrate. Metabolic activation correlated with the intensity of subjective symptoms (see Figure 60–5).

Psychosocial Factors
Psychosocial factors affecting the outcome of hallucinogen intoxication include the user’s instructional set, the environmental setting, degree of suggestibility, and personality type. The most vulnerable person exposed to LSD, for example, would be one who slipped the drug without warning, with pre-existing psychiatric illness, rigid personality traits, in an excessively stimulating environment.

Treatment
Treatment of hallucinogen intoxication with panic is easily managed with oral benzodiazepines (diazepam 20 mg or lorazepam 2 mg), which end dysphoric anxiety within 30 min. This knowledge, along with the availability of benzodiazepines in the environment, has reduced the need of psychiatric emergency interventions.

Hallucinogen Abuse

Diagnosis
The criteria for hallucinogen abuse as encoded in the DSM-IV-TR are shown below:

A. A maladaptive pattern of hallucinogen use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

1. recurrent hallucinogen use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to the substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. recurrent hallucinogen use in situations in which it is physically hazardous
3. recurrent hallucinogen-related legal problems
4. continued hallucinogen use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance

B. The symptoms have never met the criteria for Substance Dependence for this class of substance.

Assessment
The majority of patients abusing hallucinogens are diagnosed by clinical history. A mental status examination consistent with hallucinogen intoxication on more than one occasion supports the diagnosis. Unlike patients dependent on alcohol and other drugs, patients involved in hallucinogen abuse are not inclined to deny the behavior, though concurrent abuse of other drugs is not uncommon.

Epidemiology
It is likely the prevalence of hallucinogen abuse has fallen steadily in the last 30 years. This is supported by a decline in published clinical studies, and a steady decrease in hallucinogen use in secondary schools (Johnston et al. 2006).
Comorbidity
Clinical observations suggest that the habitual hallucinogen user is inclined to also abuse marijuana and psychostimulants, as opposed to opiates. Alcohol abuse is a risk since it is available as a layman’s antianxiety agent. Depression and psychosis may appear independent of life hallucinogen exposures.

Course
The natural history of hallucinogen abuse is a bell-shaped curve beginning in adolescence and declining by the midtwenties. This suggests that if hallucinogen dependence exists, it must be rare.

Differential Diagnosis
The acute effects of hallucinogens are unique, but drugs sold as LSD, e.g., are often adulterated with a second drug, or contain an entirely different drug. Thus, PCP and amphetamine congeners must be considered. Not uncommonly, a patient with paranoid schizophrenia will describe being repeatedly poisoned with a hallucinogen, but the absence of a well-described drug experience and the presence of other psychotic symptoms make hallucinogens an unlikely diagnosis.

Treatment
Clinical experience suggests that a chronic user of hallucinogens is a polydrug user. Conventional treatment of polydrug use involves an array, when indicated, of detoxification, individual and family therapy, 12-step abstinence programs, community treatment programs, pharmacotherapies, resolution of legal difficulties, and attention to comorbid illnesses.

LSD-Related Psychotic Disorders

Diagnosis

Criteria for substance-induced psychotic disorders are noted below:

**DSM-IV-TR Criteria**

**Substance-Induced Psychotic Disorder**

A. Prominent hallucinations or delusions, Note: Do not include hallucinations if the person has insight that they are substance induced.

B. There is evidence from the history, physical examination, or laboratory findings of either (1) or (2)

1. the symptoms in Criterion A developed during or within a month of substance intoxication or withdrawal
2. substance use is etiologically related to the disturbance

C. The disturbance is not better accounted for by a psychotic disorder that is not substance induced. Evidence that the symptoms are better accounted for by a psychotic disorder that is not substance induced might include the following:

- The symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent non-substance-induced psychotic disorder (e.g., a history of recurrent nonsubstance related episodes).

D. The disturbance does not occur exclusively during the course of delirium.

Note: This diagnosis should be made instead of a diagnosis of substance intoxication or substance withdrawal only when the symptoms are in excess of those usually associated with the intoxication or withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

Code specific substance-induced psychotic disorder.

292.11 amphetamine (or amphetamine-like substance), with delusions;
292.12 amphetamine (or amphetamine-like substance), with hallucinations;
292.11 hallucinogen, with delusions;
292.12 hallucinogen, with hallucinations.

Specify:

With onset during intoxication: if criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome.

With onset during withdrawal: if criteria are met for withdrawal from the substance and the symptoms develop during, or shortly after, a withdrawal syndrome.

Among the hallucinogens, LSD has been associated with the majority of, but not all, prolonged psychotic reactions following acute drug use. These have been reviewed extensively (Strassman 1984, Abraham and Aldridge 1993, Abraham et al. 1996). Psychoses are apparently rare with the abuse of botanical preparations, in all likelihood because such agents are of low potency (except for salvinorin-A), not widely abused, and often controlled by religious sanctions. By comparison, persisting psychoses have been seen following the administration of LSD to patients and experimental subjects, though this is uncommon as well (Opitz 1963, Leuner 1967, Baker 1967, McFarling 1980).

Assessment
Assessment for psychosis associated with hallucinogen use does not differ from that of acute intoxication. Other causes of psychosis should be ruled out with examination, toxicology studies to rule out other drug-induced psychosis, general
A 19-year-old man used LSD for the fourth time. In the past, his trip on LSD ran an 8-hour course. Now, however, auditory and visual hallucinations persisted over the next week. At the same time his behavior became increasingly agitated and bizarre. His speech became rapid and incoherent. He was unable to sleep. His energy was increased though he talked of committing suicide. He expressed the delusion that he had sexual relations with a pet, and that he was androgynous. He was admitted to a psychiatric hospital where he showered with his clothes on and pulled a towel rack off the wall. Four-point restraints were required. His history was negative for prior psychosis. There was no history of drug dependency. His family history was positive for depression. The patient was treated at the onset with neuroleptics that were supplemented with lithium carbonate in the fourth week. He remained disoriented, delusional, and hallucinatory until the illness remitted 2 months after his last use of LSD.

**Comment**

This case illustrates the continuum between LSD use and an acute psychotogenic reaction. Salient are signs consistent with the positive symptoms of schizophrenia including multimodal hallucinations, bizarre delusions and behavior, and thought disorder. Like other patients in this class, without predisposing factors, this man had a relatively healthy premorbid adjustment and good outcome. The patient has avoided mind-altering drugs since discharge. There has been no relapse in a 20-year follow-up.

Salient are signs consistent with the positive symptoms of schizophrenia including multimodal hallucinations, bizarre delusions and behavior, and thought disorder. Like other patients in this class, without predisposing factors, this man had a relatively healthy premorbid adjustment and good outcome. The patient has avoided mind-altering drugs since discharge. There has been no relapse in a 20-year follow-up.

### Epidemiology

### Comorbidity Patterns

The diagnosis of hallucinogen psychosis is often confounded by preexisting mood and psychotic disorders, and the abuse of other drugs and alcohol. The dually diagnosed patient with psychosis and chronic drug abuse is more often the rule than the patient presenting de novo with psychosis following the recent ingestion of an hallucinogen. Comorbidity brings with it the added clinical challenges of more frequent psychotic episodes, poor medication compliance, poor self-care, aggression, prison, and the risk of suicide (Buckley 2006).

### Course

The natural history of post-hallucinogen psychoses appears to follow a highly variable course. On one end of a spectrum of severity, an individual may suffer an acute psychotic event following drug use which then resolves over a period of days or weeks. Further along this spectrum are those patients whose recovery occurs over months, or years. Finally, there are those smaller number of patients who descend into a painful state of psychotic chronicity, made all the more poignant because the illness tends to preserve insight as his peers progress through the life cycle.

### Differential Diagnosis

The differential diagnosis of post-hallucinogen psychosis is that for any acute psychotic disorder. This includes protracted psychoses following the use of the dissociative anesthetics PCP and ketamine, amphetamines, and cocaine, schizophrenia and affective disorders, migraine, delirium from CNS infections, closed head injuries, tumors, vascular events, and the toxic effects of bromine, heavy metals, and anticholinergic drugs. Central to diagnosis is a careful premorbid history, complemented by data from friends and family on the patient’s recent medical history and behavior. Neurological examination, an acute urine for toxicological screening, and computed tomography or magnetic resonance imaging of the brain are helpful in ruling out treatable non-LSD-related psychotic disorders.

### Psychological Factors

Recent work by Bellack et al. (2006) has shown in a randomized clinical trial that behavioral treatment for dually diagnosed patients can be effective on measures of less drug use, reduced hospital stays, better retention in treatment, and quality of life.

### Treatment

Treatment of post-LSD psychoses has been described in 15 case series. Four case studies reported success with 1st generation neuroleptics (Cohen 1960, Reich and Hepps 1972, Hatrick and Dewhurst 1970, Dewhurst and Hatrick 1972), four with multiple treatments of bilateral electroconvulsive therapy (ECT) (Metzner 1969, Hatrick and Dewhurst 1970, Muller 1971, Fookes 1972), two with lithium (Horowitz...
1975, Lake et al. 1981), and one with a controlled clinical trial of the serotonin precursor 5-hydroxytryptophan (Abraham 1983b).

**Hallucinogen Persisting Perception Disorder (HPPD)**

**Diagnosis**

**Definition and Diagnostic Features**

The definition of hallucinogen persisting perception disorder according to DSM-IV-TR is shown below:

<table>
<thead>
<tr>
<th>DSM-IV-TR Criteria</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Hallucinogen Persisting Perception Disorder (Flashbacks)</strong></td>
</tr>
<tr>
<td>A. The reexperiencing, following cessation of use of a hallucinogen, of one or more of the perceptual symptoms that were experienced while intoxicated with the hallucinogen (e.g., geometric hallucinations, false perception of movement in the peripheral visual fields, flashes of color, intensified colors, trails of images of moving objects, positive afterimages, halos around objects, macropsia, and micropsia).</td>
</tr>
<tr>
<td>B. The symptoms in Criterion A cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.</td>
</tr>
<tr>
<td>C. The symptoms are not due to a general medical condition (e.g., anatomical lesions and infections of the brain, visual epilepsies) and are not better accounted for by another mental disorder (e.g., delirium, dementia, schizophrenia) or hypnopompic hallucinations.</td>
</tr>
</tbody>
</table>

Clinical Vignette 2 illustrates a number of features of HPPD.

**Assessment**

HPPD arises following the use of hallucinogenic drugs such as LSD. It may also arise following other hallucinogens, but not as commonly. The onset of symptoms occurs in the majority of cases within the first month following drug use, but spontaneous appearances of symptoms can occur months and years later. Visual symptoms predominate. They include afterimagery of objects moving through the visual field (“trails”), imagistic and geometric hallucinations, aeropsia (myriad dots in the air), pareidolia (imagery within images), and difficulty reading (Abraham 1983a). Figure 60–6 illustrates patient drawings of representative visual pseudohallucinations in HPPD. Such visual disturbances can vary in frequency from occasional to continuous. Symptoms can be acutely exacerbated by marijuana, stimulants, alcohol withdrawal, anxiety, or extreme physical activity. Other somatic symptoms difficult to characterize such as “a head feeling” and “depersonalization” are also commonly described.

**Epidemiology**

Overall, HPPD appears to occur only rarely in people who have had significant use of hallucinogens (Halpern and Pope 2003). HPPD is most likely to occur with prior LSD use, but may also occur following use of other hallucinogens.

**Comorbidity Patterns**

Clinical experience with HPPD suggests that three disorders are overrepresented comorbidly—panic disorder, major depressive disorder, and alcohol dependence—the last often being an ill-considered attempt at reducing visual disturbances. Although treatment of HPPD is often only palliative, alertness to reversible comorbid issues is crucial for a successful outcome.

**Course**

While at least 40% of LSD users report transient lingering visual effects following drug use, only a small percentage appear to develop HPPD. Among those, HPPD becomes
Figure 60–6  Drawings of hallucinations by patients with hallucinogen persisting perception disorder. These drawings of visual symptoms were made by actively symptomatic patients in a drug-free condition. Such imagery occurred to the patients on a daily basis. No patient was psychotic. Each knew that the visual disturbances were "not real." Image (A) the perception of flashes of light; (B) seeing countless dots moving in the air; (C) geometric shapes moving in swirling pattern; (D) pareidolia, in which the patient saw faces in the veneer of wood; (E) the trailing of afterimages as an arrow moved through the patient's visual field; (F) difficulty reading caused by moving afterimages of letters appearing on the paper suggesting an acquired dyslexia. (See Color Plate XIV)

chronic in approximately half (Abraham 1983a). In the remainder, recovery tends to occur at a slow rate relatively impervious to pharmacological interventions.

Differential Diagnosis
Although the typical HPPD patient tends to correctly diagnose the condition himself by consulting the DSM-IV-TR or internet sites devoted to HPPD, it is not uncommon for him to consult multiple clinicians for care before a clinical diagnosis is made. Because the symptoms are primarily perceptual, an HPPD subject may consult an ophthalmologist, neurologist, or psychologist before seeing a psychiatrist. Despite a patient's certainty about his diagnosis, the clinician is obligated to rule out other
sources of chronic organic hallucinosis, including other drug toxicities, neurodegenerative disorders, stroke, CNS tumors, infections, and head trauma. Magnetic resonance imaging of the brain is usually negative. Quantitative electroencephalography shows accelerated alpha and visual evoked potentials, especially in the posterior cerebrum.

**Etiology and Pathophysiology**

**Early Studies**

Sandison et al. (1954) first described LSD-like experiences recurring days to weeks following the ingestion of LSD. Subsequent clinical reports of this phenomenon adopted the street label of “flashbacks” to describe persisting imagery and LSD-associated affect (Rosenthal 1964, Robbins et al. 1967, Holsten 1969, Shick and Smith 1970). Anderson and O’Malley (1972) first suggested that the term “flashback” was a misnomer, since many patients described not simply flashes of imagery, but continuous visual disturbances.

**Neurobiology**

A series of studies of HPPD patients beginning in 1982 (Abraham 1982, Abraham and Wolf 1988, Abraham and Duffy 1996, 2001) provided evidence for the hypothesis that the visual symptoms in HPPD arise from chronic disinhibition of the visual apparatus (See Figure 60–7).

In a study of color perception (Abraham 1982) drug-free LSD users observing a white disk on a yellow background tended to see the disk as yellow. This suggested that in scanning the object the visual system saw yellow but could not inhibit the signal well enough to see white. A formal battery of psychophysical studies (Abraham and Wolf 1988) confirmed that drug-free LSD users had poor dark adaptation and flicker perception—both manifestations of visual disinhibition. Finally, in controlled quantitative EEG studies with HPPD patients, neural correlates of visual hallucinations were found, including stable measures of cortical disinhibition (Abraham and Duffy 1996), as well as increased synchrony in the primary visual cortex (see Figure 60–8).

Pharmacological probes comparing an intravenous benzodiazepine to an antihistamine to inhibit visual symptoms in HPPD found that the former was superior even at the lowest doses (see Figure 60–9).

Further support for hallucinogen-mediated disinhibition of neurobehavioral systems comes from animal data, in which the hallucinogenic 5-HT₂A agonist 2,5-dimethoxy-4-iodamphetamine (DOI) has been shown to disrupt sensory gating (Sipes and Geyer 1995).

**Treatment**

**Treatment Goals**

The goals of treatment are to reduce patients’ unpleasant symptoms and improve function when possible. Since comorbid substance abuse is common, addressing that in a productive way is essential. Alcohol is reported by patients to reduce their symptoms, though in one study, 22 (65%) of “psychedelic drug users” reported alcohol or marijuana triggered flashbacks (Matefy et al. 1978). Benzodiazepines have been shown in case series to be helpful. These observations make symptom relief potentially difficult to balance with possible comorbid substance abuse.

**Somatic Treatments**

Treatment is palliative. Benzodiazepines, olanzapine, sertraline, naltrexone, and clonidine have been reported to help in selected cases (Young 1997, Lerner et al. 1997, 1998, 2000, 2001, Aldurra and Crayton 2001, Alcantara 1998, Lauterback et al. 2000, for review see Halpern and Pope 2003). Benzodiazepines have been repeatedly recommended, though occasionally patients with HPPD will abuse them as a means of reducing these symptoms. One study of 16 patients receiving clonazepam 2 mg daily for 6 months showed significant and persistent improvement of HPPD symptoms (Lerner et al. 2003). Risperidone has been reported to exacerbate HPPD symptoms (Abraham and Mamen 1996). A single exposure to marijuana has been clinically observed to induce a prolonged exacerbation of HPPD. Because HPPD is also exacerbated by CNS arousal, affect, stress, and stimulants, these are to be reduced or avoided. HPPD is worse...
with one’s eyes closed, or when entering a dark environment. Thus, sunglasses, which serve to reduce the difference between outdoor and indoor luminance, may reduce HPPD symptoms when the patient enters an interior space.

**Psychosocial Treatments**
Engaging patients with ongoing comorbid substance abuse into 12-step programs or other psychotherapeutic treatments aimed at reducing substance abuse is important for overall outcome (El-Mallakh 1998).

**Issues in the Clinician–Patient Relationship**
Trust is essential in all clinical relationships. Trust is enhanced when the clinician is able to make the correct diagnosis quickly, takes the patient’s reports seriously, and is able to prescribe effective treatments. In this regard, a careful history that allows the clinician to distinguish HPPD from primary psychoses is essential. Realizing that some antipsychotic agents, e.g., risperidone, may worsen the illness, clinicians should avoid such treatments. Similarly, reports of transient symptom relief from alcohol should not be written off as an excuse to continue to abuse alcohol, but should be recognized as a risk factor for alcohol dependence and possible benefit from a careful trial of GABA-A agonists (Abraham and Fava 1999). While alcohol acutely provides some measure of anxiolysis, rebound anxiety from pathologic overuse may hasten the reemergence or worsening of HPPD overall. Evidence, as noted above, exists that alcohol can trigger HPPD, despite patient self-reports of symptom amelioration with alcohol.

**Treatment Refractory Patients**
There is a paucity of research in the area of treatment of HPPD (Halpern and Pope 2003). Although HPPD appears to be permanent in many cases, slow but steady recovery in some appears possible over a period of years. Beneficial factors appear to be avoidance of drugs and alcohol, enduring relationships and productive work. One of us (HDA) has followed a cohort of HPPD patients who have functioned well in their families and careers for three decades. It is common for a recovering HPPD patient to admit that visual disturbances are ever present but that involvement in meaningful tasks of daily life push the symptoms to the periphery of awareness.

**MDMA**

**Diagnosis**

**Definition and Diagnostic Features**
The definition of hallucinogen abuse according to DSM-IV-TR is shown above.

**Assessment**
A typical MDMA user is a college student (Pope et al. 2001, Peroutka et al. 1988). In a survey of 14,000 college students in 119 American colleges, MDMA users were more likely to use marijuana, smoke cigarettes, and engage in binge alcohol consumption (Strote et al. 2002). They were also more likely to have multiple sex partners (Strote et al. 2002). They considered arts and parties important, but they were not academic underachievers (Strote et al. 2002).
In a study of 132 pregnant MDMA users compared with 122 non-users, several characteristics stood out. The MDMA-using women were younger (23.2 versus 31.2 years old, \( P < 0.0001 \)), experienced more unplanned pregnancies (84.2 versus 54.3%, \( P < 0.05 \)), and were more likely to be single parents (57.0 versus 18.3%, \( P < 0.001 \)) (Ho et al. 2001). Over half abused alcohol (66.4% versus 37.3%, \( P < 0.001 \)), and a greater fraction abused other drugs (not significant) (Ho et al. 2001). Over a third reported some psychiatric problem, but only 6.5% had a psychiatric diagnosis (Ho et al. 2001). While other drug use appears more common in subjects using MDMA, it is of interest to note that in over one third, their first exposure to illicit drugs is in the setting of MDMA use (Gervin et al. 2001).

Epidemiology

Despite its existence for nearly 90 years, there was no significant nonmedical use of MDMA until the late 1970s. While there is some evidence that a very small number of people intentionally or unintentionally sampled MDMA during the 1960s (see Gaston and Rasmussen 1972, Shulgin and Shulgin 1991), MDMA use began in earnest during or shortly after therapists began experimenting with it as an adjunct to psychotherapy. Early use of MDMA was generally in small groups in private settings (Peroutka et al. 1988). Accurate epidemiologic data was not collected until 1983 when SAMHSA’s Office of Applied Studies started to include specific questions about MDMA in their National Survey on Drug Use and Health and it wasn’t until 1989 that the National Institute on Drug Abuse’s Monitoring the Future survey also collected such data. By 1997, about 2.8% of a sample of college students reported using MDMA (Strote et al. 2002). College is the first time people are likely to begin use of MDMA (Randell 1992, Cuomo et al. 1994). In a survey of 14,000 college students at 119 American colleges by the Harvard School of Public Health College Alcohol Study, there was a 69% increase in use between 1997 and 1999 (from 2.8% to 4.7%) (Strote et al. 2002). Use by all age groups has over the same time, the use of drugs like MDMA. Because of concern that their presence may constitute “evidence” of violation of this Act, organizations, such as DanceSafe, are not typically invited anymore into clubs and rave events to offer their “harm reduction” education materials and pill testing for the presence of MDMA. Concomitant drug use is also more common in raves (Gerhard 2001, Gervin et al. 2001, Strote et al. 2002). These include alcohol, marijuana, and opiates. Furthermore, the term “ecstasy,” which was originally used to refer specifically to MDMA (Hamid et al. 2005), has grown to refer to other related compounds such as MDA and 3,4-methylenedioxyethylamphetamine (MDE or “Eve”) (Gerhard 2001) and to “club drugs” in general. The combination of multiple drug use increases the risks of adverse consequences associated with MDMA use (see below).

Prior to its placement on Schedule I by the DEA, MDMA was tested as an adjunct to psychotherapy (Shulgin and Nichols 1978, Greer and Tolbert 1986, 1998). In this setting, a dosage of 50–200 mg (with modal doses ranging from 100 to 150 mg), with a booster of 50–75 mg several hours later, was used. There are no published controlled studies of the use of MDMA in psychotherapy. However, there is one open study of 29 subjects in which the dosage used was 75–150 mg after a 6-h fast with an offered second dose of 50–75 mg. All subjects reported positive attitudinal and emotional changes (Greer and Tolbert 1986). Twenty-two felt that their insight into their own psychopathology was enhanced. Twenty-one subjects in couples treatment reported increased closeness and communication with their partner (Greer and Tolbert 1986). All subjects reported minor adverse consequences similar to those reported by recreational drug users. Two controlled experiments are ongoing in the United States with MDMA-assisted psychotherapy. One is examining this experimental treatment for refractory PTSD patients, the other is evaluating whether this may be helpful with advanced stage cancer patients struggling with treatment-refractory anxiety disorder secondary to a general medical condition.

Comorbidity Patterns

Other drug use, particularly marijuana (98%) and alcohol (65%), is very common in subjects using MDMA (Wish et al. 2006, Breen et al. 2006). Tobacco use is also quite common (Boyd et al. 2003). Individuals who use high doses of MDMA are more likely to abuse other agents (Clatts et al. 2005). For approximately one-third of MDMA plus other substance users, MDMA was their initial illicit drug used in one study (Gervin et al. 2001). Tobacco and alcohol are the key “gateway” drugs to other intoxicant experimentatation.

Comorbid psychiatric conditions are also more common in MDMA users (Martins et al. 2006). Over half (55%) of MDMA users in one study had a comorbid psychiatric condition with 35.3% experiencing at least one lifetime major depression and 25.4% with antisocial personality disorder (Flack et al. 2006). The majority of MDMA users...
with mental illness report mental health problems prior to initiation of MDMA use (Lieb et al. 2002).

Course
In general, people who use MDMA do not display a pattern of tolerance and increasing drug use. MDMA users generally limit the frequency of use of the drug. Most report limiting use of MDMA to twice per month or less. Fridays and Saturdays are the most common days for ingestion because users say they need one day to recover after use (Peroutka et al. 1988, Liester et al. 1992). More frequent use is associated with a loss of the desired effect of the drug (Gerhard 2001). Approximately 6 years after initiation of MDMA use, individuals begin to reassess their use pattern (Murphy et al. 2006). However, some individuals may use very high doses of MDMA or use it frequently. Such use, particularly when mixed with other drugs, may lead to adverse physical or cognitive consequences of MDMA use. Subjects with problematic MDMA use tend to use higher doses of the drug, including in binges, and are more likely to have both a personal and a family psychiatric history (Soar et al. 2006). While there is clearly an interplay between psychiatric problems and adverse consequences, most people who have been diagnosed with depression report having the depressive disorder diagnosis prior to MDMA use (Guillot and Greenway 2006, Huizink et al. 2006, Lieb et al. 2002).

Differential Diagnosis
Other agents, such as MDA and alpha-ethyltryptamine (AET), may have similar effects to MDMA.

Differences in Developmental, Gender, and Cultural Presentations
Females appear to be more sensitive to some of MDMA's acute effects compared to males (Liechti et al. 2001), an effect sometimes seen in rodents (Palenicek et al. 2005, Walker et al. 2007). Males are more likely to be heavy users of MDMA than females (Milani et al. 2004); however, women are more likely to experience psychopathology (Milani et al. 2004). Women using MDMA believe it reduces weight gain and increases their exercise duration, but do not use it primarily for weight control (Curran and Robjant 2006).

MDMA use is associated with increases in impulsivity. In heterosexual males, this is associated with an increase in the number of sex partners, in females it may contribute to significantly higher rate of unplanned pregnancies. In homosexual men, it may present with increased rate of unprotected anal sex (Ho et al. 2001, Clatts et al. 2005, Novoa et al. 2005). Homosexual subjects are also at greater risk for using “club drugs” which include MDMA (Lampinen et al. 2006).

Etiology and Pathophysiology

Neurobiological Factors
Former chronic ecstasy users (an average of 527 tablets) have higher self-reported depression as measured by the Beck Depression Inventory than non-drug-using controls (MacInnes et al. 2001). A meta-analysis of the small number of studies examining this issue also found a small depressogenic effect with prolonged MDMA use but noted that in most studies controlling for concomitant drug use was inadequate (Summall and Cole 2005). The predictors of developing this depressive syndrome are maximum quantity of pills consumed over a 12-h period and mild and frequent life stress (MacInnes et al. 2001). Pre-MDMA onset of a depressive disorder may contribute to and confuse the etiology of this depressive picture (Guillot and Greenway 2006, Huizink et al. 2006). Heavy MDMA use has also been associated with higher rates of psychopathology, including obsessive and compulsive behaviors, anxiety, somatization, and loss of libido (Parrott et al. 2001). The cause-and-effect relationship between MDMA use and these psychiatric syndromes is unclear, but since these syndromes involve serotonergic mechanisms, additional investigation into these potential long-term sequelae is warranted.

MDMA users have been noted to have problems with memory, attention, reasoning, and impulse control (Krytchal and Price 1992, Allen et al. 1993, Parrott and Lasky 1998, McCann et al. 1999, Gouzoulis-Mayfrank et al. 2000, McGuire 2000, Reneman et al. 2000, 2001b, Bhattachary and Powell 2001, Verkes et al. 2001, Medina and Shear 2006). Heavy MDMA users (>55 life time tablets) suffered long-lived (after one year of abstinence) cognitive decline while moderate users (<55 life time tablets) did not have persistent cognitive sequelae (Reneman 2006a). Memory deficits can persist for at least 2 years after cessation of MDMA (Ward et al. 2006). In a study of 22 recent MDMA users, 16 ex-users (abstinent for over 1 year), and 13 normal controls who underwent the Rey Auditory Verbal Learning test, the immediate recall score (47, 48, and 60, respectively, P = 0.001) and the delayed recall score (9.8, 10.1, and 13.1, respectively, P = 0.003) were significantly less in recent and remote MDMA users than in normal controls, suggesting that the memory dysfunction persists for more than 1 year (Reneman et al. 2001b). The memory difficulties persisted despite recovery of serotonergic abnormalities on SPECT (Reneman et al. 2001b). Similarly, 15 MDMA users were tested initially after a 2-week abstinence, and again a year later (Zakzanis and Young 2001). The subjects who continued to use MDMA experienced a progressive decline of both immediate and delayed recall (Zakzanis and Young 2001). In 21 heavy users, 21 moderate users, and 20 nonusers, there was a “statistically significant but clinically small” decline in memory and prolongation of reaction time (Verkes et al. 2001). Heavy users were more affected than moderate users (Verkes et al. 2001).

In 80 subjects, which included novice users, regular users, and ex-users compared to nonusers, all MDMA subjects had decreased verbal fluency, decreased immediate prose recall, and decreased delayed prose recall, but no change in visual recall (Bhattachary and Powell 2001). The number of days since last MDMA use and total lifetime dose accounted for over 50% of the variance, suggesting both a dose–response effect and a possible recovery process (Bhattachary and Powell 2001). The relative sparing of visual recall is of interest since decline in 5-HT1A receptor density after MDMA use is a characteristic of all brain regions except the occipital cortex in rats and humans, where MDMA upregulates the receptor density (Reneman et al. 2002a). Nevertheless, studies of neurocognition and MDMA use, particularly studies that report verbal memory deficits, are often challenged by problems of statistical power and the confounds of demographic, comorbid drug use, and premorbid psychopathology.

Serotonergic loss is evident through several markers which include reduced brain serotonin, 5-hydroxyindoleacetic acid (5-HIAA), and the serotonin transporter (Schmidt et al. 1986, Battaglia et al. 1987, Schmidt 1987, Cummins et al. 1987, O'Hearn et al. 1988, Slikker et al. 1988, 1989, Acquas et al. 2001).

Immunocytochemical studies suggest that serotonergic neurons are damaged, but the cell bodies are preserved (O'Hearn et al. 1988, Wilson et al. 1989, Molliver et al. 1990). Recovery from MDMA-induced serotonergic damage occurs. While rodents appear to recover (Scanzello et al. 1990), in monkeys the damage persists at least 7 years (Ricartre et al. 1992, Fischer et al. 1995, Hatzidimitriou et al. 1993), in humans, serotonergic changes after repeated MDMA use are evident through several different types of studies. CSF 5-HIAA levels may be reduced in MDMA users (McCann et al. 1994). This effect is more pronounced in women than in men (McCann et al. 1994) and possibly represents changes in serotonergic turnover rather than persistent neurotoxicity (Mechan et al. 2005). N-acetyl aspartate (NAA, a marker of cellular health) was quantified with magnetic resonance spectroscopy in 15 MDMA users and 12 age-matched controls. NAA was significantly reduced in the frontal cortex, but not in the parietal or occipital cortex (Reneman et al. 2001c, 2002b). This effect appears to be dose related (Reneman et al. 2002b). In a prospective study of low dose MDMA, no decrease in the NAA signal was noted (de Win et al. 2007). The extent of previous MDMA use and frontal cortical neuronal loss were significantly associated, indicating that cortical damage is directly related to extent of MDMA use. McCann et al. (2005), utilizing PET methodology, found global reductions in serotonin transporter expression in some MDMA users. Semple et al. (1999) found similar results with SPECT in MDMA users compared to controls. Reneman et al. (2001a, 2001b) also used SPECT and [123I]-2beta-carbomethoxy-3beta-(4-iodophenyl) tropane, which binds to both the serotonin and dopamine transporters with high affinity (Laruelle et al. 1994, Lew et al. 1996), and found that serotonin transporter binding was reduced in female heavy users but not male users (Reneman et al. 2001a, 2001b). This provides independent support to the finding that women are more susceptible to damage by MDMA. In subjects abstinent from MDMA for over 1 year, recovery of serotonin transporter density to normal levels was evident (Reneman et al. 2001a).

The confounding of human MDMA studies from other drugs presents an enduring difficulty in the literature. Croft et al. (2001) studied 18 pure cannabis abusers, 11 that use both cannabis and MDMA, and 31 subjects who use neither cannabis nor MDMA. They report that both cannabis and MDMA/cannabis users showed equal impairment in memory, learning, work fluency, speed of processing and manual dexterity compared to normal controls (Croft et al. 2001). This suggests that reports of cognitive decline attributed to MDMA use may be due to concomitant use of cannabis. Similar confounding has been observed in MDMA users with concomitant abuse of alcohol, marijuana, opioids, and inhalants (Medina and Shear 2006). Confounding is not supported as an explanation by animal or cellular studies (Krystal and Price 1992, Allen et al. 1993, Parrott and Lasky 1998, McCann et al. 1999, Gouzoulis-Mayfrank et al. 2000, McGuire 2000, Reneman et al. 2000a, 2000b, Bhattachary and Powell 2001, Zakzanis and Young 2001, Stone et al. 1986, Simantov and Tauber 1997, Hatzidimitriou et al. 1999, Taffe et al. 2001). A review of this question by Gouzoulis-Mayfrank and Daumann (2006) concluded that neural injury in humans can occur in heavy MDMA use, but that the evidence cannot be considered definite until preexisting traits and polydrug abuse are addressed. These very factors have been tackled in one study (Halpern et al. 2004) where neurocognitive testing was given to 23 MDMA users and 16 nonusers all of whom had little to no experience with other drugs (including alcohol) and in which premorbid functioning was sought through questions about parental education and employment and subject conduct in childhood. Overall, MDMA users did not differentiate in performance from the controls on any measure, but a post hoc median split revealed that the heavy users (N = 11) did statistically worse on measures of impulsivity and mental processing speed. This study did not find the type or pattern of deficits as noted in the other studies above on polydrug MDMA users and is most suggestive that confounding has impacted human data collection on this issue of MDMA and neurocognitive health.

Metabolism and Pharmacokinetics
MDMA is usually present in two optical isomers. The dextrorotatory form, S-(+)-MDMA is more potent in the CNS than the levorotatory form R-(-)-MDMA (Anderson et al. 1978). MDMA is broken down by N-demethylation, O-dealkylation, deamination, and conjugation. MDMA is metabolized into MDA (which itself is sometimes used recreationally), 4-hydroxy-3-methoxymethamphetamine (HMMA), and the main metabolite 3,4-dihydroxymethamphetamine (HHMA). (Helminlin et al. 1996, Fallon et al. 1999, Maurer et al. 2000, Pizarro et al. 2004). MDA can also be metabolized to HHMA and HMMA, which are either excreted unchanged in the urine or are glucuronidated prior to urinary excretion (Helminlin et al. 1996, Fallon et al. 1999, Maurer et al. 2000, de la Torre et al. 2004). HHMA plasma levels will peak at approximately the same concentration as the parent drug but ultimately accounts for only 17.7% of total drug recovered in a 24-h urine collection (Segura et al. 2001). The combination of MDMA and HHMA accounts for over 60% of total drug in the urine after 21 h (Helminlin et al. 1996).

Maximum plasma MDMA concentrations are achieved 2–4 h after ingestion. In a study of two subjects who had previously used MDMA, the level peaked between 2 and 6 h at greater than 20 ng/mL (Pacifi ci et al. 2001). Mas et al. (1999)
found that the half-life of a lower dose (75 mg) was shorter (7.7 h) than a higher dose (125 mg at 8.6 h). Measured peak plasma concentrations were 130.9 ng/mL after 75 mg and 236.4 ng/mL after 125 mg (Mas et al. 1999). Similarly, de la Torre et al. (2000) found a dose-related peak plasma concentration in extensive metabolizer variants of CYP 2D6. (Extensive metabolizers possess enzymes that metabolize the drug at a faster rate than the general population.)

The peak MDMA concentration increases disproportionately in a nonlinear fashion compared to the metabolites. This suggests that the demethylating enzyme step is saturable with increasing MDMA dose (Figure) (de la Torre et al. 2000).

The more active S- (+)-MDMA isomer is metabolized faster (Fallon et al. 1999, Cho et al. 1990) and more extensively (Fallon et al. 1999, Fitzgerald et al. 1989) than the levorotary form, so that the half-life of S- (+)-MDMA is 73.8 to 210 min while the half-life of R- ( -) -MDMA is 100.7 to 350 min (Fallon et al. 1999, Verebey et al. 1988, Pacifici et al. 2001). The mean plasma concentration of the levorotary form is 2.4 times higher than the S- (+) isomer and a significantly greater amount is excreted unchanged in the urine (Fallon et al. 1999). MDMA in brain microsomes is metabolized primarily through O-dealkylation (Lin et al. 1992). Iso- mer-specific brain metabolism has not been studied.

Because MDMA is metabolized by CYP 2D6, some researchers expressed concern that MDMA might pose a risk in CYP 2D6 poor metabolizers (Schifano 2004). However, it appears that poor metabolizers are not greatly affected by MDMA (de la Torre et al. 2004, Segura et al. 2005). As well, Gilhooly and Daly (2002) failed to find higher numbers of poor metabolizers among ecstasy-related fatalities.

Pharmacology
MDMA causes a calcium-independent release of serotonin (5-HT) from nerve endings (Johnson et al. 1986, McKenna and Peroutka 1990) with concomitant inhibition of serotonin reuptake (Steele et al. 1987). The dextrorotary enantiomer, S- (+)-MDMA, is more potent than the levorotary isoform (Johnson et al. 1986, Steele et al. 1987, Hiramatsu and Cho 1990). MDMA has a very low affinity for postsynaptic serotonin receptors (Lyon et al. 1986, Bettaglia et al. 1988). It also increases dopamine release (Yamamoto and Sapanos 1988, Hiramatsu and Cho 1990, Nash et al. 1990) but this effect is less than the effect on serotonin (Johnson et al. 1986, Steele et al. 1987, McKenna and Peroutka 1990). There is also a dose-related increase in cortical acetylcholine (ACh) release (Acquas et al. 2001) but this may be mediated by serotoninergic and dopaminergic mechanisms (Nair and Gudelsky 2006a) and may not have significant impact on ACh function (Nair and Gudelsky 2006b). The cortex is more sensitive to MDMA than the striatum: 3.2 mg/kg MDMA increases ACh release in the cortex some 141%, but only 32% in the striatum (Acquas et al. 2001). It is believed that the effects on 5-HT mediate most of the psychological effects of MDMA.

Indirect evidence of serotonergic involvement is found in neuroendocrine studies. In animals, MDMA treatment produces a profound increase in serum corticosterone and prolactin (Nash et al. 1988, Poland et al. 1997). This effect is attenuated or blocked by pretreatment with the serotonin neurotoxin, p-chlorophenylalanine (Nash et al. 1988), suggesting that the process is mediated by serotonin. MDMA at doses of 75 mg is associated with an increase in serum cortisol, while doses greater than 75 mg increase both cortisol and prolactin (Grob et al. 1996, Mas et al. 1999). The prolactin response to serotonin agonists, such as fenfluramine, is generally blunted in MDMA users compared to controls (Price et al. 1989, Verkes et al. 2001, Gerra et al. 1998, 2000, Gouzoulis-Mayfrank et al. 2002). However, since concomitant drug use, particularly marijuana, is so common in ecstasy users, all these studies are confounded by potential cannabis effects (Gouzoulis-Mayfrank et al. 2002). Consequently, this may be one of the reasons that studies using L-tryptophan as a neuroendocrine challenge have been negative (L-tryptophan is a serotonin precursor and increases brain serotonin levels) (Price et al. 1990, McCann et al. 1994). Alternatively, L-tryptophan challenge may be insufficiently sensitive. Many variables can influence neuroendocrine findings. In a naturalistic study of nightclub attendees, Wolff et al. (2006) found increased oxytocin only in people with detectable levels of MDMA, suggesting a role for this hormone both in increased feelings of affiliation and in changes in sodium regulation.

Genetic Factors
Since MDMA has weak serotonin reuptake inhibitory action (Steele et al. 1987), the effect of serotonin transporter polymorphism has been investigated. Individuals with the short form of the serotonin transporter (homozygotes for the short form, ss) had reduced discrimination between between high and low probabilities of winning and a reduced reflection effect on gains-only/losses-only trials compared to short form homozygotes that do not use MDMA (Roiser et al. 2006). In other words, MDMA use may interact with serotonin transporter polymorphism to effect decision-making strategies (Roiser et al. 2006). However, serotonin transporter polymorphism did not predict the long-term cognitive decrements that can occur in heavy MDMA users (Reneman et al. 2006a).

Acute Positive Psychological Effects
Subjects utilizing MDMA frequently report positive mood and emotional effects. They report increased self-esteem, high energy, relaxation, and joy (Camí et al. 2000, Liechti et al. 2001, Harris et al. 2002, Tancer and Johanson 2003). In the dose range of 1.75 to 4.18 mg/kg, most subjects report euphoria, increased physical and emotional energy, and a heightened sensual awareness (Downing 1986). In a double-blind, placebo-controlled study of 13 MDMA-naïve subjects given 1.7 mg/kg (about 119 to a 70 kg person), MDMA induced enhanced mood, a sense of improved well-being, increased emotional sensitivity, increased energy, and a heightened sensory awareness (Vollenweider et al. 1998). Similar findings were reported in another double-blind study (Grob et al. 1996). In a double-blind, placebo-controlled comparison study of MDMA 75 mg, MDMA 125 mg, and amphetamine 40 mg, all subjects reported an euphoria, but this feeling was greatest in the MDMA 125 mg group (Camí et al. 2000). In another blinded comparison of escalating MDMA doses and m-chlorophenylpiperazine (mCPP), a serotonin releasing agent, both drugs produced euphorogenic and hallucinogenic effects to a similar degree (Tancer and Johanson 2001). Participants reported feeling more talkative
and friendly after MDMA (Tancer and Johanson 2003, Vollenweider et al. 1998). The one attempt to assess feelings of empathy or closeness to others failed to detect it after 1.5 mg/kg MDMA (Harris et al. 2002), but the assessment consisted of two questions drawn from a larger questionnaire.

One of the most common reasons for using ecstasy is its effect on sexual drive. More than 90% of users report a moderate to profound increase in sexual desire and satisfaction (Zemishlany et al. 2001). Orgasm is reported as delayed but more intense (Zemishlany et al. 2001). However, in males, erection can be impaired in as many as 40% of subjects (Zemishlany et al. 2001).

**Acute Adverse Psychological Effects**

Acute adverse effects include anxiety as well as alterations in perception, facilitated recall, and facilitated imagination (Cami et al. 2000, Vollenweider et al. 1998). MDMA acutely affects simple visual recall without affecting the ability to spot small changes in complex visual changes as noted in the first pharmacological challenge study involving change blindness (Ramaekers et al. 2006). As well as increasing positive mood, MDMA can increase anxiety and negatively experienced derealization (Cami et al. 2000, Harris et al. 2002, Liechti et al. 2001, Tancer and Johanson 2001), including anxiety related to feeling out of control. Altered perceptions (Siegel 1986, Vollenweider et al. 1998, Mas et al. 1999) may be experienced by some MDMA users as a negative consequence of the drug. In a double-blind, placebo-controlled study of 13 MDMA-naïve subjects, most reported anxiety, a mild depersonalization or derealization, a moderate thought disorder, and poor coordination (Vollenweider et al. 1998).

In a study of 21 previous MDMA users given doses ranging from 1.75 to 4.18 mg/kg (an average of 175 mg for a 70 kg person), 40% reported impaired decision-making ability and 30% reported decreased mathematics performance (Downing 1986). When given as an adjunct for psychotherapy, all 29 subjects reported some adverse event (Greer and Tolbert 1986). Fatigue was the most common psychosomatic complaint (Greer and Tolbert 1986). Worsening or precipitation of panic attacks has been reported by several authors in different settings (Greer and Tolbert 1986). At least 49 cases of acute psychosis associated with MDMA use have been reported (Creighton et al. 1991, Cox 1993, Bone Pina et al. 2000, Milas 2000, Vaiva et al. 2001, Van Kampen and Katz 2001, Vecellio et al. 2003) including 32 in a 6-month follow-up study (Landabaso et al. 2002). In most of these cases there is use of concomitant substances. In several cases, the psychosis was long-lived for at least months. A wide range of impulsive or irrational behaviors have been associated with MDMA use (Dowling et al. 1987, Cadier and Clarke 1993, Hooft and Van der Voorde 1994, Cifasi and Long 1996). Most of these reports were published because they resulted in a major medical problem or death. MDMA use is associated with an increase in impulsive behaviors (Ho et al. 2001, Strote et al. 2002) and a reduced ability to measure risk when making risky decisions (Morgan et al. 2006).

**Physical Consequences of MDMA Use**

MDMA increases blood pressure and heart rate (Grob et al. 1996, Lester et al. 2000, Mas et al. 1999, Vollenweider 1998). Chief side effects include decreased appetite, difficulty concentrating, impaired gait or balance, and tight jaw or jaw clenching (Harris et al. 2002, Liechti et al. 2001). Women more frequently reported experiencing side effects when compared with men (Liechti et al. 2001), while men showed a significantly greater increase in heart rate and body temperature. Humans exhibit complications that are related to both the sympathomimetic and serotonergic properties of MDMA. These include nausea, vomiting, anorexia, hypertension, palpitations, diaphoresis, headaches, hyperreflexia, tachycardia, and hypertension (Dowling 1986, Vollenweider et al. 1998).

In a double-blind, placebo-controlled study involving change blindness (Zemishlany et al. 2001). Orgasm is reported as delayed but more intense (Zemishlany et al. 2001). However, in males, erection can be impaired in as many as 40% of subjects (Zemishlany et al. 2001).

**Physical Consequences of MDMA Use**

MDMA increases blood pressure and heart rate (Grob et al. 1996, Lester et al. 2000, Mas et al. 1999, Vollenweider 1998). Chief side effects include decreased appetite, difficulty concentrating, impaired gait or balance, and tight jaw or jaw clenching (Harris et al. 2002, Liechti et al. 2001). Women more frequently reported experiencing side effects when compared with men (Liechti et al. 2001), while men showed a significantly greater increase in heart rate and body temperature. Humans exhibit complications that are related to both the sympathomimetic and serotonergic properties of MDMA. These include nausea, vomiting, anorexia, hypertension, palpitations, diaphoresis, headaches, difficulty walking, muscle aches and tension, hot and cold flashes, urinary urgency, nyctagmus, blurred vision, insomnia, and dry mouth (Downing 1986, Greer and Tolbert 1986, Peroutka et al. 1988, Liester et al. 1992, Solowij et al. 1992, Topp et al. 1999). The common complaints of trismus and bruxism may reflect MDMA enhancement of serotonin activation of the 5-HT 1B receptors of the trigeminal motor nuclei (Tancer and Johanson 2001).

In a survey study of 44 experienced MDMA users at an average dose of 120 mg (range 50–700 mg), all reported muscle tension, 91% reported diaphoresis, and 77% reported blurred vision and ataxia (Siegel 1986). Muscle tension in the form of trismus is a commonly reported adverse event (Downing 1986, Vollenweider et al. 1998). A transient gait disturbance was also common in a group of subjects who received MDMA as a psychotherapeutic adjunct, 21 MDMA users who received doses averaging 175 mg for a 70 kg subject, and 13 MDMA-naïve healthy controls (Downing 1986, Vollenweider et al. 1998). Other frequently reported acute physical consequences of MDMA use are hyperreflexia (Dowling 1986), tachycardia, and hypertension (Grob et al. 1996).

Twenty-four hours after a single dose of MDMA averaging 119 mg in a 70 kg MDMA-naïve subject, a detailed evaluation revealed the presence of decreased energy, decreased appetite, restlessness, insomnia, and trismus (Vollenweider et al. 1998).

The acute motoric abnormalities have been related to driving impairment. A review of the literature noted at least 18 reports of driving impairment in people using MDMA (usually along with other drugs) (Logan and Couper 2001). These reports include six users stopped for speeding, eight for erratic driving, and five involved in collisions (Logan and Couper 2001). At least two MDMA-related deaths have been associated with automobiles (Hooft and Van der Voorde 1994, Cifasi and Long 1996). In a screen of intoxicated drivers in Norway, 2% of impaired drivers had MDMA in their blood, but 98% of these drivers had other drugs as well (Hausken et al. 2004). However, in a study of driving ability (using a simulator) after either MDMA alone or MDMA used with other drugs, MDMA alone was not associated with significant impairment, but combined drug use resulted in poor driving ability (Brookhuis et al. 2004). Notably, drivers with MDMA alone were unaware of taking increased risks while in the simulator (Brookhuis et al. 2004). A team in the Netherlands has performed a number of studies of effects of MDMA on driving skills (Kuybers et al. 2006, Lamers et al. 2003, Ramaekers et al. 2006). They found that 75 mg MDMA reduced weaving but impaired ability to estimate the time it took for an obscured object to move from one place to another, and they failed to find any effects of MDMA the day after drug administration (Ramaekers et al. 2006).

MDMA has been associated with a wide range of somatic toxic events. These include thrombotic or
hemorrhagic strokes (Harries and DeSilva 1992, Gledhill et al. 1993, Hughes et al. 1993, Manchanda and Connolly 1993, Rothwell and Grant 1993, Auer et al. 2002), leukoencephalopathy (Bertram et al. 1999), myocardial infarction (Qasim et al. 2001), arrhythmias (Dowling et al. 1987, Henry et al. 1992), and pneumothorax (Mazur and Hitchcock 2001). The wide range of manifestations suggests that most of these cases are either idiosyncratic or related to impurities remaining from the synthetic process. Since much of the MDMA supply is synthesized in small “basement” laboratories, the quality control of the manufacturing process may not be adequate. The results of weekly drug sampling in the Netherlands found that most (75% in 1996), but not all, “ecstasy” pills actually contained MDMA (Spruit 2001). The percentage dropped in 1997 and increased again in 1998 (Spruit 2001). About one-third of the pills contained amphetamine or other derivatives (Spruit 2001). These non-MDMA drugs might explain some of the heterogeneity of medical complications of “ecstasy” use. Certainly, the cases of hepatotoxicity (Henry et al. 1992, Shearman et al. 1992, Ijzermans et al. 1993, Khakoo et al. 1995, Ellis et al. 1996, Andreu et al. 1998, DeCarlis et al. 2001, Lawler et al. 2001, Brnic et al. 2006) and aplastic anemia (Marsh et al. 1994, Clark and Butt 1997) most likely are idiosyncratic or secondary to contaminants.

Cases of severe medical illness or death due to electrolyte and fluid abnormalities (Maxwell et al. 1993, Kessel 1994, Matthai et al. 1996, Hall 1997, Ajaelo et al. 1998, Magee et al. 1998, Holmes et al. 1999, O’Connor et al. 1999) and cases of multiple organ system failure (Henry et al. 1992, Brown and Osterloh 1987, Chadwick et al. 1991, Campkin and Davies 1992, Roberts and Wright 1993, Lehmann et al. 1995, Coore 1996, Demirkiran et al. 1996) are less likely due to MDMA use directly. These complications may be related to the specific environment in raves. In raves, people are exposed to hot, crowded environments with high-beat music invoking energetic dancing. In association with increased body temperature caused by MDMA (Liechti and Vollenweider 2000), dehydration and its consequences are increased at raves. Crowding has been shown to increase amphetamine toxicity in animals, a phenomenon labeled aggregation toxicity (Chance 1946, Hohn and Lasagna 1960). A similar phenomenon may occur in crowded raves in humans.

MDMA may also cause serotonergic hyperstimulation and produce a fatal serotonin syndrome-like (Sternback 1991) illness (Demirkiran et al. 1996, Mueller and Korey 1998).

Social/Environmental Factors
Unlike many drugs of abuse, which are frequently used alone, MDMA is almost always used in the company of others. Most MDMA users report positive mood and emotional effects as they relate to others. In a survey of 44 experienced MDMA users, subjects reported a greater capacity for empathy, communication, and understanding (Downing 1986). MDMA use now is most common in large club gatherings.

Treatment
There have been no studies examining the treatment of MDMA abuse or of its consequences. The issue of how a practitioner may help his/her patient discontinue MDMA abuse is never addressed in the literature. This is due to the rarity of presentation of subjects seeking treatment for MDMA addiction. Nonetheless, MDMA has abuse potential. Baboons will self-administer MDMA (Lamb and Griffiths 1987). Rhesus monkeys trained to self-administer cocaine, prefer MDMA (Beardsley et al. 1986). However, rhesus monkeys allowed to self-administer MDMA over an 18-month period reduce their administration over time (Fantegrossi et al. 2004). Also 50% of these animals will administer MDMA at a rate higher than they had administered cocaine. In several animal species that are trained to discriminate amphetamine from saline, MDMA easily substitutes for amphetamine (Glennon and Young 1984, Kamien et al. 1986). Animals treated with high-dose MDMA (40 mg/kg for 4 days) exhibit increased cocaine self-administration with rates twice those of saline-treated controls (Fletcher et al. 2001). Intracranial self-administration of MDMA lowers the threshold to a rewarding electrical stimulus to the medial forebrain bundle (Hubner et al. 1988). These data suggest that MDMA may facilitate the abuse of other substances. Indeed, humans who use MDMA rarely use the drug alone, and concomitant substance abuse then is likely (Wish et al. 2006, Breen et al. 2006). Thus, recommendation of 12-step programs and addressing other substance use is one reasonable approach.

Treatment Goals
As with most issues regarding substance treatment, abstinence is generally the goal. “Controlled” MDMA use is actually possible (Peroutka et al. 1988, Liester et al. 1992), but MDMA abuse has led some users turn to heroin to “come down” (Gervin et al. 2001). In chronic users, drug education should reinforce the value of abstinence but also add information to reduce possible risks associated with future drug use.

Somatic Treatments
There are no somatic treatments available that will reduce craving or MDMA abuse. However, somatic treatments are recommended for the consequences of MDMA abuse.

Psychosis secondary to MDMA has been treated with antipsychotic agents; one study suggests that olanzapine is effective (Landabaso et al. 2002). Second generation antipsychotic agents with significant 5-HT2C and 5-HT2A blockade (all atypicals with the exception of quetiapine) may be reasonable to use. Similarly, because of its ability to block postsynaptic 5-HT2C and 5-HT2A receptors (Samunaris et al. 1997), mirtazapine has been recommended for depression associated with MDMA and used in at least one case (Fetter 2005). There have been no studies of anticholinergic agents or memantine in the treatment of cognitive dysfunction of MDMA.

Special Factors Influencing Treatment
MDMA use during pregnancy may have consequences to the fetus. In studies with pregnant rats given MDMA, there is a documented entry of MDMA into the fetal compartment at significant levels (Campbell et al. 2006).

Introduction

The term *inhalant abuse* is used to describe a variety of drug-using behaviors that cannot be classified by their pharmacology or toxicology but are grouped based on their primary mode of administration. Although other substances can be inhaled (e.g., tobacco, marijuana with or without phencyclidine, and even heroin or crack), volatilization is not the primary mode of administration; therefore, they do not fall into this classification. Solvent and propellant products vary by region and country, and also over time. With such a diverse group of substances included in a category, it is difficult to identify the chemical substances most prominently used by inhalant abusers. We will attempt to identify and classify abused chemical substances and the products containing them, characterize primary disorders and toxicities and discuss treatment issues. Types of products containing abused inhalants can be grouped as follows: (1) industrial or household cleaning and paint-type solvents including paint thinners or solvents, degreasers or dry cleaning solvents, solvents in glues, art or office supply solvents such as correction fluids, and solvents in magic markers (gasoline is similar to these products); (2) fluorocarbon propellant gases used in household or commercial products, in electronic (personal computer, office equipment) cleaners or as refrigerant gases; (3) butane/propane hydrocarbons are present in household aerosol sprays such as paint, hair, and fabric protector sprays, or in cigar lighters; (4) medical anesthetic gases such as ether, chloroform, halothane, and nitrous oxide (which is also available in whipped cream dispensers (e.g., whippets) and as octane boosters for car racing) and (5) aliphatic nitrates. Except for nitrites, the foregoing compounds affect the central nervous system (CNS) directly. As nitrites are mostly used as sexual enhancers rather than as mood alterants, the discussion of “inhalant abuse” will refer herein to the other volatile substances. Also, the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) excludes anesthetics from the inhalant-related disorders section. Nationally, and in other surveys, anesthetics are included, as almost all of the inhalants act physiologically as would any anesthetic. With limited studies of the different issues, the authors do not limit their discussion to either category and try to discuss the issues utilizing the most current and available data.

Substances Inhaled

Volatile substances (or inhalants) are ubiquitous. The practice of inhalation to produce euphoria can be traced to the ancient Greeks (Carroll 1977). At the turn of the 19th century, Humphrey Davy in England, experimenting with the newly discovered gas nitrous oxide, discovered its mind-altering effects (Bergman 1991). Ether and, later, chloroform parties occurred frequently; at one time, ether was suggested for treatment of alcohol addiction. These anesthetics are still abused (Hutchens and Kung 1985, Kringsholm 1980, Krenz et al. 2003). The 20th century brought the use of gasoline and along with it many other volatile mixtures including many solvents, cleaners, aerosols, degreasers, and glues. Table 61–1 enumerates many of the solvents (frequently noted on the labels) contained in products currently used for recreational purposes. Despite the widespread availability and inhalation of these substances, it was not

It is difficult to identify which chemical in a product is the one which produces the “high” (may be more than one), or to quantitate the extent of abuse by collectively grouping all the products containing any one substance to evaluate the relative degree of that substance in inhalant dependency. With that caveat, a tentative order of preference of select chemicals will be delineated using historical human and animal reports and surveys.

1. Toluene is the most commonly used substance and is found in many commercial products. It is “often considered” to be nontoxic in spite of many studies/reports to the contrary. The use of pure toluene on the streets attests to its popularity; this is enhanced by the availability of pure toluene, both in hardware stores and at warehouses. (2) If you group together cigarette lighter gases and all aerosols which contain butane propellants (most now do), the abuse of “butane-type” gases is very high (see below), especially the use of lighter-refill gas cartridges. (3) Gasoline for many reasons, mostly availability, has been and still is widely abused. (4) What has been most prevalent in the past, fluorocarbons, are not now widely used in the US as a propellant. However, with the manufacture of partly hydrogenated-fluorocarbons, this could increase their availability in many aerosol products (note as in PC sprays). Another related abuse is that asthma inhalers (containing fluorocarbons) have been used to get
“high” (Thompson et al. 1983, O’Callaghan and Milner 1988). (5) Nitrous oxide has been a favorite for many years in many situations, from the release of this gas from whipped cream aerosols to “whippets” (small compressed nitrous oxide “bombs”) to commercial compressed tanks of N₂O₃ sold by the “balloon-full” to “college-age” groups. (6) Lastly, chlorohydrocarbons (nonfluoro) have been a problem in the past in the dry cleaning industry, as was the abuse of correction fluid products; they are now present in head cleaner products (the latter product reportedly produced a “mental status change” and walking instability in a subject [Finch and Lobo 2005]).

The practice of “sniffing,” “snorting,” “huffing,” “bagging,” or inhaling to get high describes various methods of inhalation (Sharp et al. 1992). These terms refer to the inhalation of volatile substances from (1) filled balloons, (2) bags, and (3) soaked rags and/or sprayed directly into oral orifices. Abusers can be identified by various telltale clues such as organic odors in the breath or clothes, stains on the clothes or around the mouth, empty spray paint or solvent containers, and other unusual paraphernalia. These clues may enable one to identify a serious problem of solvent abuse before it causes serious health problems or death.

It is now widely recommended that one should not mix alcohol and other sedatives. For example: “Degreaser’s flush” (so described because of a flushing of the face) was observed when occupational workers left their degreasing vats to visit the local “pub” for alcohol (Pardys and Brotman 1974, Stewart et al. 1974). Also, heavy drinking has been associated with occupational toluene exposure (Antti-Poika et al. 1985). Both humans and rats have been noted to be thirsty when exposed to toluene and alcohol (Pryor et al. 1985, Kira et al. 1988). It is not yet been determined that either substance has the ability to encourage the use of the other.

Few studies have characterized the “high” produced by inhalants. Interestingly, a study by Evans and Raistrick (1987) summarized the “sniffer’s” perceptive feelings when they inhaled two quite different substances, butane gas or toluene. Moods, thoughts, hallucinations (except tactile sensations), and colors appeared similar with either compound. However, time passed slowly with butane and more rapidly with toluene. This one study would indicate that these different chemical substances give similar-type reinforcements; this may be one reason why products containing them are widely abused. Also, different occupations from anesthesiologists to painters have a potential for abusing substances easily available to them (Yamashita et al. 1984, Nordin et al. 1988, Jacob et al. 1989, Krause and McCarthy 1989). That inhalants are also abused by professionals, including medical personnel (Spencer et al. 1976, Jastak 1991, England and Jones 1992), and college students demonstrates a greater diversity of this dependency than is often appreciated. This may be indicative that a “typical” inhalant abuser pursues a high similar to the “light-headedness” produced by early stage anesthesia. Many inhalants/solvents would produce anesthesia if sufficient amounts are inhaled with the proper amounts of oxygen present. As with any anesthetic, death is possible and too often occurs with these solvents/gases.

**Epidemiology**

**Prevalence**

Inhalant abuse is a worldwide problem. Many countries are now evaluating the abuse of solvents (Adelekan 1989, Alvarez et al. 1989, Pedersen et al. 1989, Kozel et al. 1995, Butt et al. 2004, Galduroz et al. 2005, Dell et al. 2005, Hedhili et al. 2005, Field-Smith et al. 2006, Carra et al. 2006). The extent of the international problem of inhalant abuse was discussed at a conference held in September 2005; synopses of the presentations are available online at: http://international.drugabuse.gov/downloads/Inhalant_Summary.pdf. In the United States two long-standing surveys have tracked the rates and patterns of use. The Monitoring the Future (MTF) study (Johnston et al. 2006) employs anonymous surveys given in schools to 8th, 10th, and 12th graders while the National Survey on Drug Use and Health (NSDUH) conducts interviews with a sample of persons over the age of 12. The most current rates of inhalant use from these studies are shown in Table 61–3. The general trend is for inhalant use to decrease with increasing age reflecting the general perception that inhalants are a preferred drug by younger children. The MTF reports that approximately 1.5% of 8th graders have used inhalants on a weekly basis. There are no documented reasons why younger children use inhalants more often but it is likely that approximately 1.5% of 8th graders have used inhalants on a weekly basis.
that accessibility and price are factors. The fact that lifetime prevalence decreases with grade level is somewhat anomalous since in any given population this number should increase or at least remain level as a cohort ages. A possible explanation for this is that, as described below, chronic inhalant users experience multiple personal and social problems, including dropping-out of school and are not present to be surveyed in the upper grades. Further, there may be problems with recall and the stigma attached to inhalant use; also there may be a realization as one matures that the earlier concept of what “high” means was not correct. Thus, older students negate in their minds the earlier report of inhalant abuse as a “high” experience.

Source: *Johnston et al. (2006); †http://monitoringthefuture.org/.

The MTF data show a distinct pattern of inhalant use among adolescents over time. Using the lifetime prevalence measure as an indicator of overall exposure to inhalants, there was a gradual increase in use from 1975 through 1995, followed by a decline until 2003. Since 2003, there are signs that use may now be increasing again.

To establish the rates of diagnosable disorders, Wu et al. (2004) examined the results of the NSDUH. For adolescents ages 12–17 they found a 0.2% rate for DSM-IV-TR diagnoses of abuse and 0.2% rate for dependence. However, among the smaller cohort of youth who had used in the past year the rates were much higher at 6% and 4%, respectively. There were no differences by gender. Using the same procedures and database for adults, Wu and Ringwalt (2006) detected a 10% lifetime prevalence rate for inhalant use. Of the 0.5% who had used in the past year there was a diagnosis rate of 6.6% for abuse and 1.1% for dependence. Importantly, the patterns and correlates of inhalant use differed between adults and adolescents. The most commonly used inhalants by adults were nitrous oxide and poppers (amyl, other organic, nitrates) while adolescents preferred glue and gasoline. Further, adults did not use inhalants as often and there were fewer negative correlated behaviors or problems.

While the above percentages appear relatively small, the National Household Study on Drug Use and Health estimated that there were 178,000 persons in the US in 2000 with a diagnosis of inhalant abuse or dependence. There is evidence to suggest that very few of these people are in treatment (Beauvais et al. 2002a). The lack of specific treatment protocols, the reluctance of abusers to present to treatment and a widespread attitude that inhalant abusers are refractory to treatment may account for this.

**Sociodemographic factors**

Wu et al. (2004) examined the National Household survey for sociodemographic factors associated with past year inhalant abuse or dependence for 12–17-year-olds and concluded.

“Adolescents who met criteria for abuse or dependence reported coexisting delinquent behavior, multiple drug abuse and dependence and utilization of mental health services for other emotional problems. Thus, inhalant abuse and dependence may be a marker of general vulnerability rather than an isolated problem. This vulnerability may be influenced by individual as well as family factors, as evidenced by the association between foster care and inhalant use disorder.”

They further found a strong relationship between disorders and early first use, prompting the recommendation that prevention activities must begin very early. Interestingly, while other studies have shown higher prevalence rates (particularly lifetime use) of inhalant use among certain minorities, specifically Mexican-Americans and American Indians, these differences did not show up for abuse and dependence diagnoses. With respect to American Indian adolescents, Beauvais et al. (2004) have demonstrated that while historically prevalence rates have been high, these rates have diminished over the past decade to where they are equivalent to non-Indian youth. African American adolescents have lower overall levels of drug use and, consistent with this, have the lowest levels of inhalant use.

Both for adults (Wu and Ringwalt 2006) and adolescents (Wu et al. 2004) few differences in inhalant use are found for family income, challenging the commonly held notion that inhalant use is restricted to lower income individuals. There is also some slight indication that, among adults, lifetime prevalence is higher among those with higher education. This finding must be viewed with caution since the questions asking about inhalant use included the use of nitrous oxide and nitrates, substances often excluded from the category of “inhalants.” A further finding is that for adults inhalant use is more common in the urban areas while for adolescents it is more common in the small metro and rural areas. This may be due to lesser accessibility of other drugs in less populated areas, or alternately, as described above, the greater popularity of nitrous oxide and nitrates among adults in urban areas.

The disorders classified in this chapter are classified under the inhalant-related disorders section in DSM-IV-TR and are subdivided into two groups: inhalant use disorders and inhalant-induced disorders.

**Inhalant Use Disorders**

The criteria of DSM-IV-TR has been recently studied and compared to DSM-III-R and *International Classification of Diseases, Tenth Revision* (ICD-10) (Howard et al. 2001). They identified certain inhalant abusers because, overall, these individuals are a very heterogeneous population that needs to be characterized and studied based on the type of inhalant. There are different ethnic groups associated with inhalant use as with any drug use, but there are also a variety of types of gases/solvents which are abused differently and are associated with different but yet unidentified disorders. Abusers of nitrous oxide or nitrates may have different dependencies than those abusing paint sprays. The groups studied by Howard et al. (2001) were predominantly
solvent abusers. The conclusion from the above study was that the DSM-III-R was a better diagnostic system for inhalant abuse or dependence than is DSM-IV-TR.

Inhalant Abuse
This diagnosis is probably more characteristic of children, adolescents, and industrial workers who occasionally intentionally inhale products they work with to get intoxicated. Inhalant use among younger people has been shown to be episodic and faddish. School surveys have shown wide differences from year to year within the same schools. It is characteristic of the imitative behavior of this developmental period that occurs when something “new” comes along and there is strong pressure to try it and be accepted. Much of this is minor experimentation that quickly wanes. However, as noted below, a single instance of inhalant use can be fatal, most often due to cardiac arrhythmia or anoxia. Those young people whose use is more extended can at times be diagnosed with abuse. School work can be disrupted and there may be absences from jobs. Because of their volatile and explosive nature, the use of inhalants is inherently dangerous and the physical and mental impairment can lead to a variety of injuries from accidents. Legal problems are usually rare because of the secretive nature of inhalant use and ambiguity over their legal status. Finally, use may continue despite frequent family disruption. It must be noted, however, that much use is surreptitious and the family may be unaware. Nonetheless, the impairment from abuse can disrupt family dynamics regardless of whether or not the family is aware. Older abusers who use products of their occupation are at primary risk from injury but clearly job performance and family dynamics can be affected.

Inhalant Dependence
Evidence for the basis of inhalant dependence is slowly emerging. This is differentiated from the more extreme state of anesthesia related to the CNS depressant actions and the toxicity of these substances. Reinforcing actions of “inha- lants” have been studied in humans exposed to anesthetics (Beckman et al. 2006); these actions were also critically reviewed by Balster (1998). A more recent study compared two different classes of anesthetics (isoflurane/sevoflurane and nitrous oxide) regarding subjective effects (Beckman et al. 2006). The “fluranes” were more sedative in action whereas nitrous oxide produced more pleasant, euphoric-like actions. More groups are beginning to focus on the cellular basis of dependence as contrasted/compared to anesthesia in humans. MacIver’s group has examined the similarities between toluene and anesthetics, finding that both increase GABA-mediated inhibitory synaptic transmission in the hippocampus, and this likely contributes to a disruption of learning. In contrast, toluene did not depress glutamate synapses like anesthetics do (McDonald et al. 2003, MacIver 2006). Recent MRI studies in animals, given toluene acutely, have measured altered glucose uptake in the frontal cortex, as well as in other regions, including the hippocampus and thalamus (Schiffer et al. 2006). They stated that the cortical areas were more susceptible than striatal areas in altering place “preference” or “dependence” to toluene; Riegel et al. (2003) identified the nucleus accumbens involvement in locomotor hyperactivity. In these and other studies, GABAergic and/or dopaminergic (Schiffer et al. 2006, Riegel et al. 2003, Gerasimov et al. 2002) systems seem to be strongly involved in reward mechanisms. This correlates with the earlier studies of ataxia and pyramidal tract dysfunction described in humans by Rosenberg and colleagues. In addition the insula area of the brain has been linked to addiction (Naqvi et al. 2007); a recent case of butane exposure also identifies this area (Kile et al. 2007) in describing the patient’s encephalopathy and relates this to his dependence on this inhalant. Which system and area of the brain is the primary, or important, reward system for these different states of dependence, as contrasted to the state of anesthesia, remains open to further study.

More recent studies, however, indicate that toluene (and other inhalants) acts rapidly due to the rapid absorption through the lungs, thus leading to a quick euphoria; all this makes it likely that they will produce a strong physical dependence. Thus a mild withdrawal syndrome often occurs in 10 to 24 hours after cessation of heavy use and lasts for several days. Symptoms include general disorientation, sleep disturbances, headaches, muscle spasms, irritability, nausea, and fleeting illusions. However, this is not an easily identified or a characteristic withdrawal syndrome that is useful for many practitioners in a clinical setting. The need to continue use is undeniably strong in many individuals. Specific treatments for inhalant dependence, other than the drug therapy and/or psychotherapy used for other drug dependencies, need to be developed.

Binging for extended periods of time is a common pattern among inhalant dependent individuals and it is likely that this is beyond their original intention. There are little data on whether the dependent patient will report attempts to stop or cut down their use. These people rarely voluntarily present for treatment of inhalant use and usually surface due to some other problem, usually public intoxication or accidents. Many adolescent users are identified by parents or other family members upon discovering a large number of containers containing inhalants (e.g., many empty hair spray cans found in a bedroom). Inhalants are readily available so it is unlikely that there is a great deal of time obtaining them; however, recovery from their effects can take an extended time. Clearly, long-term intoxication can interfere with social, occupational or recreational activities. Many inhalant dependent patients are well aware of the physical harm their use is causing but display an unusual sense of indifference.

Inhalant-Induced Disorders
The primary disorder is inhalant intoxication, which is characterized by the presence of clinically significant maladaptive behavioral or psychological changes (e.g., belligerence, assaultiveness, apathy, impaired judgment, impaired social, or occupational functioning) that develop during the intentional short-term, high-dose exposure to volatile inhalants (diagnostic criteria A and B in DSM-IV-TR). The maladaptive changes occurring after intentional and unintentional exposure include disinhibition, excitement, light-headedness, visual disturbances (blurred vision, nystagmus), incoordination, dystarthis, an unsteady gait, and euphoria. Higher doses of inhalants may lead to depressed reflexes, stupor, coma, and death, sometimes caused by cardiac arrhythmia. Lethargy, generalized muscle weakness, and headaches may occur some hours later depending on the dose.
Psychiatric Disturbances Associated with Organic Solvent Abuse

Earlier studies were conflicting regarding the issue of comorbid psychiatric conditions among inhalant users. However, a series of larger and more recent studies have shown more consistency and conclude that generally inhalant users experience higher levels of psychiatric and social problems. In a nationally representative sample (N = 73,396) of adults, Wu and Ringwalt (2006) found significantly elevated levels of serious mental illness (including drug use and alcoholism) and higher levels of usage of treatment for these problems among those who had used inhalants in the past year. These findings were confirmed in another large national study by Wu and Howard (2006a). In this study the rates for women who had used inhalants were higher than for men. Earlier reports stated that inhalant users derived from psychiatric emergency room admittants differed significantly from matched other drug users in that they displayed significantly more self-directed destructive behavior, as well as some degree of recent suicidal and homicidal behavior (Korman et al. 1980). Cognitive measures of these and other inhalant abusers supported the antisocial and self-destructive nature of inhalant abusers (Korman et al. 1981, Oetting and Webb 1992). This is supported by another study of “autoerotic deaths” observed for inhalant abusers (Jackowski et al. 2005). Overall, there is accepted knowledge that long-term solvent abusers are among the most difficult to work with based on antisocial traits; also, it is likely that inhalants prevent their continued growth and development (Oetting et al. 1988, Oetting and Webb 1992). Another study identified child abuse occurred in those who extensively used inhalants (Fendrich et al. 1988). In an England study in a regional assessment center, solvent-abusing male adolescent delinquents were more depressed than other drug abusers (Jacobs and Ghodse 1988) and in a Turkish study, Evren et al. (2006) discovered significantly elevated rates of depression and anxiety disorders among adults diagnosed with inhalant dependency when compared to users of other drugs and nondrug users. In an earlier study, Dinwiddie et al. (1990) also found higher rates of depression, bipolar disorder, alcoholism and antisocial personality disorder among 130 inhalant users compared to nonusers. Underscoring the antisocial personality disorder association among inhalant users, 10 out of the 11 inhalant abusing patients examined by Dinwiddie et al. (1987) had such a diagnosis.

A similar pattern emerges among studies of adolescents. Using the NSDUH, Wu et al. (2004) found that 10.6% of adolescents (aged 12–17) who had used inhalants in the past year met the criteria for abuse or dependence with no gender difference. When compared to the remainder of the sample, these groups exhibited higher levels of treatment for mental problems, higher rates of abuse of other drugs and delinquency. Using the same database as above, Wu et al. (2004) examined the subgroup that had used both inhalants and marijuana and determined that this adolescent group had also used three or more other types of drugs (73%) and were diagnosed with abuse or dependence for alcohol (35%) and another drug (39%). Sakai et al. (2004) studied an inpatient and day care drug treatment population and compared patients diagnosed with inhalant abuse or dependence to (a) those who had used inhalants but did not have a diagnosis and (b) those adolescents who had never used inhalants. When compared to both groups, inhalant diagnosed adolescents had significantly more diagnoses for other drugs, higher levels of major depression, more suicide attempts and higher levels of abuse and neglect. In a study of incarcerated youth, similar results were reported by Howard et al. (2007). Two other studies show that diagnosed inhalant users have higher levels of conduct disorder (Sakai et al. 2006b) and are more likely to use heroin and other injection drug use (Wu and Howard 2007).

Etiology and Pathophysiology

Toxicology of Inhalant Abuse

The majority of inhalant abusers are never seen in a hospital or outpatient facility. Some of the more common acute syndromes of the intoxicated state are listed in Table 61-4. Although many do not need medical attention related to their inhalant habit, of those who do, many often die before reaching the hospital as a result of asphyxia, cardiac
arrhythmia, or related overdose effects after inhaling fluorocarbons, low-molecular-weight hydrocarbon gases (butane, propane), nitrous oxide, gasoline or other solvents including toluene during either the first or a subsequent episode (Bass et al. 1970, Wason et al. 1986, Al-Alousi 1989, Mathew et al. 1989a, Siegel and Wason 1990, Garriott 1992, Scerri et al. 1992, Fitzgerald et al. 1993, Groppi et al. 1994, Broussard et al. 1997, Rohrig 1997, Bowen et al. 1999, Hobara et al. 2000, Beauvais et al. 2002b, Martinez and Ballesteros 2005, Gaulier et al. 2003, Xiong et al. 2004, Field-Smith et al. 2006). Unusual reports of inhaling exhaust fumes for “pleasure” have even been noted; some result in death (Martinez and Ballesteros 2006). Death may also occur after inhalation of toluene-containing substances as a result of metabolic acidosis or related kidney failure if left untreated (Garriott 1992). Although it is not common, anesthetics abused by medical personnel or others have also been a cause of death; death related to nitrous oxide use is often due to asphyxia (Clark et al. 1985, Suruda and McGlothlin 1990, Wagner et al. 1992).

### Clinical Manifestations After Chronic Inhalant Abuse

Chronic high-level exposure to organic solvents occurs in the inhalant abuse setting at levels several thousand times higher than in the occupational setting and results in numerous irreversible disease states. Some toxicities have been validated through animal studies; others have been only tentatively correlated with certain substances. Table 61–5 describes several well-characterized disorders and identifies the solvent when corroborated by animal studies. Some substances have been strongly correlated with the development of a disorder through numerous case studies. The following discussion briefly describes these conditions and the important associated symptoms.

### Neurological Sequelae of Chronic Inhalant Abuse

The nervous system may be affected at many levels by organic solvents as well as other neurotoxic substances. Because of their nonfocal presentation, neurotoxic disorders may be confused with metabolic, degenerative, nutritional, or demyelinating diseases (Schaumburg and Spencer 1987). This is illustrated in the setting of chronic toluene abuse, which clinically may resemble the multifocal demyelinating disease, multiple sclerosis, in the findings on neurological examination (Lazar et al. 1983, Fornazzari et al. 1983, Hormes et al. 1986). In addition, neurotoxic syndromes rarely have specific identifying features on diagnostic tests such as computed tomography, magnetic resonance imaging (MRI), or nerve conduction studies (Schaumburg and Spencer 1987). As a result, subjects who only inhale for a limited time or to a limited extent may be difficult to diagnose. High-level chronic inhalant abuse, on the other hand, produces a specific MRI picture with a combination of diffuse white matter changes and low signal intensity in the basal ganglia and thalamus (Rosenberg et al. 1988a, Caldmeyer et al. 1993, Unger et al. 1994, Yamanouchi et al. 1995, 1997, Kamran and Bakshi 1998, Rosenberg et al. 2002).

Many organic solvents produce nonspecific effects (e.g., encephalopathy) after exposure to extremely high concentrations; a few produce relatively specific neurological syndromes with chronic administration. Two specific neurotoxic syndromes, a peripheral neuropathy and an ototoxicity, are well correlated with organic solvents. Most common, however, is a clinical syndrome consisting of cognitive impairment, cerebellar ataxia, and spasticity syndrome (Lazar et al. 1983, Fornazzari et al. 1983, Hormes et al. 1986). In addition, a myopathy may occur alone or in combination with any of these clinical syndromes.

### Central Nervous System Involvement (Encephalopathy)

Microencephalopathy has emerged as a possible embryopathic syndrome in infants of women exposed during pregnancy to solvents containing toluene (Arnold et al. 1994, Pearson et al. 1994). Recently, encephalopathies have been observed following inhalation of butane-type products (a fluorocarbon-152A was also present in one case). The first study showed increasing cerebral atrophy by MRI after three weeks (Doring et al. 2002); the second was unremarkable as measured by MRI three days after admission (Harris and Mirza 2005).

Most reports emphasized the cerebellar and cognitive dysfunction, with most cases showing combined impairment of cerebral and cerebellar functions as well as pyramidal changes. Neurological abnormalities varied from mild cognitive impairment to severe dementia, associated with elemental neurological signs such as cerebellar ataxia, corticospinal tract dysfunction, oculomotor abnormalities, tremor, deafness, and hyposmia. Cognitive dysfunction was the most disabling and frequent feature of chronic toluene toxicity and may be the earliest sign of permanent damage. Dementia, when present, was typically associated with cerebellar ataxia and other signs (Hormes et al. 1986).

Rosenberg et al. (1988b, 2002) utilized MRI to study the brains of chronic abusers of toluene-containing substances and interpreted the encephalopathy as a diffuse CNS white matter change with the following abnormalities: (1) diffuse cerebral, cerebellar, and brain stem atrophy; (2) loss of differentiation of the gray and white matter throughout the CNS; and (3) increased periventricular white matter signal intensity on T2-weighted images (Filley et al. 1990). These MRI measures seemed to correlate with the extent of exposure and the impairment of the individual’s capabilities as measured on several neuropsychological tests (Filley et al. 1990). Others (Xiong et al. 1993, Caldmeyer et al. 1993, Yamanouchi et al. 1995, 1997, Kamran and Bakshi 1998) corroborated these findings.

In a recent study, Rosenberg et al. (2002) extended their earlier observations on the MRI and cognitive abnormalities in both inhalant abusers and a comparison group of other drug abusers. Interestingly, both groups had significant and equally severe cognitive deficits, which did not demonstrate a dose–response relationship in the inhalant group, but abnormalities on MRI did reveal a strong dose–response relationship with inhalant abuse.

MRI results (Unger et al. 1994) may suggest a possible mechanism for the abnormalities in the basal ganglia and thalamus. The MRI analyses of eight chronic toluene abusers revealed diffuse white matter changes and marked hypointensity in the basal ganglia and thalamus, all seen on T2-weighted images (Figure 61–1). Thus, the hypointensity of the basal ganglia and thalamus on T2-weighted magnetic resonance images of brains of chronic toluene abusers may be related to partitioning of toluene into the lipid membranes in these areas. Recent MRI studies of these and other cortical areas (Aydin et al. 2003, Takebayashi et al. 2004) confirmed the above as well as observed changes in the ratios of choline/creatine in the basal ganglia in “toluene” abusers.

Pathology
Few detailed pathological studies have been done (Escobar and Aruffo 1980, Rosenberg et al. 1988a, Kornfeld et al. 1994). The predominant feature in these studies is that of a leukoencephalopathy. A study of three cases (Kornfeld et al. 1994)—one of which was previously reported by Rosenberg et al. (1988a)—found pathological
changes similar to those in adrenoleukodystrophy, a rare hereditary disorder affecting the white matter. Gross pathological study revealed a patchy loss of myelin (Figure 61–2). The overall pathological study revealed a demyelinating process grossly manifest as brain atrophy, including macrophages containing unusual cytoplasmic bodies with an increase of long-chain fatty acids similar to that seen in adrenoleukodystrophy (Kornfeld et al. 1994). These findings suggest that toluene is a white matter toxin (similar to that reported for multiple sclerosis by Filley 1999).

Central Nervous System Involvement Possibly Related to Lead
Toxicities similar to those already noted may be caused by tetraethyllead (or its metabolite triethyllead) after prolonged or extensive inhalation of gasoline (Robinson 1978, Seshia...
et al. 1978, Valpey et al. 1978, Coodin et al. 1980, Prockop and Karampelas 1981, Goldings and Stewart 1982, Remington and Hoffman 1984, Eastwell 1985, Reese and Kimbrough 1993, Goodheart and Dunne 1994, Maruff et al. 1998, Cairney et al. 2004). The subject was reviewed well by Tenenbein (1997). Even with the elimination of lead products from gasoline in the US, the use of unleaded gasoline, which contains some of the previously described solvents, still produces similar encephalopathies. In cases in which high lead levels still may be observed, hallucinations and disorientation, dysarthria, chorea, and convulsions may be reported (Table 61–6). The symptoms have also included moderate to severe ataxia, insomnia, anorexia, slowed peripheral nerve conduction, limb tremors, dysmetria, and sometimes limb paralysis. In most cases the electroencephalogram is normal, but in severe states an abnormal to severely depressed cortical electroencephalogram is observed. Because many of these symptoms in the early stages of the disease can be reversed by chelation therapy with ethylenediaminetetraacetic acid, dimercaptol, or penicillamine, it is important to check the serum lead levels in any chronic inhalant abuser.

Otoxicity

Sensorineural hearing loss (Rybak 1992) is one of the more commonly occurring clinical neurotoxic syndromes related to inhalant abuse, along with a related equilibrium disorder (Sasa et al. 1978). Neural conduction, most readily diagnosed by brain stem auditory evoked responses, was abnormal in several case studies (Biscaldi et al. 1981, Metrick and Brenner 1982, Lazar et al. 1983, Ehayi and Freeman 1983, Rosenberg et al. 1988b, Morrow et al. 1992). These studies suggest that brain stem auditory evoked responses would detect early CNS injury related to toluene or other solvent inhalation at a time when the neurological examination and MRI scans are normal. Brain stem auditory evoked responses may be a sensitive screening test for monitoring individuals at risk from toluene exposure and for early detection of CNS injury. Although specific in revealing abnormalities characteristic of CNS involvement in chronic inhalant abuse, brain stem auditory evoked responses revealed abnormalities in less than 10 individuals of a chronic inhalant abuse population (Levisohn et al. 1992).

The hearing loss was originally classified as one of high frequency (it probably still is for humans). It is now more clearly delineated as a midfrequency hearing loss when measured in rats (or guinea pigs) exposed to solvents (Crofton and Zhao 1993, Jaspers et al. 1993, Lataye et al. 2003). A recent study of rats observed no change in the outer hair cells after exposure to trichloroethylene (TCE) but revealed a loss of spiral ganglion cells in the middle turn of hair cells (Fechter et al. 1998). As hearing loss has been identified in humans exposed to high levels of toluene, inhalant abusers using these types of chemicals should be provided good auditory evaluations.

This neuropathy can be produced in days after high exposures of animals to specific solvents and is considered to originate with the destruction of cochlear cells, which contributes to a central conduction pathology as observed in the human studies noted earlier (Pryor et al. 1983, Rebert et al. 1983). Because of the quantitative animal model available, Pryor’s group (Pryor 1995) has conducted a structure–activity study of many solvents in an effort to define the basic moiety responsible. Table 61–7 lists the different compounds and their activities. Niklasson et al. (1993) also analyzed the effects of some of these compounds on the vestibular function and correlated the changes with nystagmus in humans. A recent paper by Fuente and McPherson 2006 presents a thorough review of the human and animal literature on this.

Other Cranial Nerve Involvement

A study of four subjects (Maas et al. 1991) supported earlier observations of pendular nystagmus and related eye legation.

movement disorders in sniffers of various solvents. Oculomotor dysfunction and tremor were seen only in severely affected individuals (Hormes et al. 1986). Optical neuropathy (Keane 1978, Takeuchi et al. 1981, Elyai and Freeman 1983, Channer and Stanley 1983, Rosenberg et al. 1988a, Takeuchi 1988, Kiyokawa et al. 1999) and oculomotor dysfunction (Lazar et al. 1983, Maas et al. 1991, Poblano et al. 2000) have been observed after exposure to toluene-containing substances, pupillary damage after exposure to TCE (Feldman et al. 1985), and optical neuritis after methyl ethyl ketone (MEK) exposure (Berg 1971). Hollo and Varga (1992) suggested that visual function measures may be useful in detecting early toxic effects in solvent abusers. All of these neuropathies can be identified with specific cranial nerves (Table 61–8).

These changes have yet to be specifically correlated with TCE or other chemicals (Ödkvist et al. 1980). Optic damage needs to be corroborated through animal studies. A study of the effects of TCE exposure in rabbits for 12 weeks measured a decreased amplitude of visual evoked responses; the responses slowly returned to normal a couple of hours after exposure (Blain et al. 1992).

Hexane is not usually considered a CNS toxin; however, some clinical studies have indicated that n-hexane affects the CNS. Also, experimental animal studies have shown that n-hexane causes axonal degeneration in the CNS (Schum-burg and Spencer 1976, Bruhn et al. 1981, Frontali et al. 1981). Clinically, cranial neuropathy, spasticity, and autonomic dysfunction occasionally occur (Altenkirch et al. 1982). Of all these possible actions, animal studies have demonstrated only the optical-toxic effects of 2,5-hexanedione, a toxic metabolite of hexane, in rats (Backstrom and Collins 1992). Until these issues are further clarified through human and animal studies, n-hexane should be primarily considered a peripheral nervous system toxin.

Anosmia is an often described syndrome of inhalant abuse. It would be expected that solvents would diminish the olfactory responses; however, it has seldom been studied. Mergler and Beauvais (1992) found that olfactory perception was reduced after 7 hours of exposure to toluene and returned to normal a couple of hours after cessation of exposure. Anosmia or hyposmia was detected on clinical examination utilizing simple bedside measures in chronic inhalant abusers (Hormes et al. 1986).

### Trigeminal Neuropathy

One neurological manifestation associated with TCE intoxication is a slowly reversible trigeminal neuropathy (Ruijten et al. 1991, Feldman et al. 1992). Cranial neuropathies were noted after general anesthesia with TCE more than 40 years ago. Individuals developed paresthesia around the lips, which then spread to involve the entire trigeminal distribution bilaterally. Motor weakness also occasionally occurred. Resolution of the trigeminal neuropathy occurs slowly, which is thought to indicate segmental or nuclear trigeminal involvement.

There has been a long-term controversy about whether or not unmetabolized TCE causes trigeminal neuralgia or the neurotoxicity is due to dichloroacetylene, an environmental breakdown product of TCE (Laurore 1993, Lash and Green 1993). The incidence of trigeminal neuralgia in humans can be disputed; however, animal studies do demonstrate the production of trigeminal neuralgia by TCE, as well as dichloroacetylene (Barret et al. 1992). There are no reports of trigeminal neuropathy noted for solvent abusers despite common inhalation of TCE from different products (Levy 1986).

### Myeloneuropathy

Nitrous oxide is not an organic solvent; however, it is widely abused by adolescents (Schwartz and Calihan 1984, Wagner et al. 1992), adults (Wagner et al. 1992, Brett 1997, Butzkueven and King 2000, Waters et al. 2005) and professional personnel (Jastak 1991, Vishnubhatk and Beresford 1991, Gillman 1992). Nitrous oxide is a common anesthetic widely used in dentistry; it is also used as a propellant for whipped cream. High levels of nitrous oxide exposure produce a myeloneuropathy with both central and peripheral components, even in the presence of adequate oxygen (Layzer 1978, Pema et al. 1998, Maze and Fujinaga 2000). The symptoms include numbness and weakness in the limbs, loss of dexterity, sensory loss, and loss of balance. The early neurological features indicate sensorimotor polyneuropathy; however, with persistent abuse, a myelopathy with severe spasticity may develop. There is also a combined degeneration of the posterior and lateral columns of the spinal cord resembling that in vitamin $B_{12}$ deficiency.
patients. The relationship of vitamin B\textsubscript{12} and methionine is activated by nitrous oxide, primarily at the level of the enzyme methionine synthase, which needs vitamin B\textsubscript{12} to function (Nunn 1987). This enzyme is important in the maintenance of the myelin sheath (Flippo and Holder 1993). Flippo and Holder (1993) noted that paresthesia and other neuropathic symptoms resulting from spinal cord degeneration were produced after prolonged anesthesia in vitamin B\textsubscript{12}-deficient patients. The relationship of vitamin B\textsubscript{12} and methionine has been recently reviewed (Toohey 2006). Administration of vitamin B\textsubscript{12} (or folinic acid) dramatically aids recovery of these surgical patients and may assist recovery in solvent abusers (Vishnubhakat and Beresford 1991), especially once the myelopathy appears. The use of methionine should also be considered (Fujinaga and Baden 1994). Recent studies have identified the role of GABA receptors in mediating these neurologic actions; thus, use of GABA agonists may be useful in some treatment regimens (Maze and Fujinaga 2000, Jevtovic-Todorovic et al. 2000).

In regard to dependence on nitrous oxide, studies of mice selectively bred for alcohol dependence showed a cross-dependence on nitrous oxide (Belknap et al. 1987). These studies also observed handling-induced convulsions shortly after cessation of nitrous oxide, which could be prevented by either alcohol or nitrous oxide. This might indicate a physical dependence on nitrous oxide that needs to be dealt with in treatment of this drug abuse state.

**Peripheral Neuropathy**

Two organic solvents were identified as neurotoxins after an investigation of peripheral neuropathies in an industrial setting when the solvent methyl isobutyl ketone was replaced by methyl butyl ketone (MBK) (Allen et al. 1975). Cases of \textit{n}-hexane polyneuropathy have been reported both after occupational exposure (Herskovitz et al. 1971, Mendell et al. 1974, Mallov 1976) and after deliberate inhalation of vapors from products containing \textit{n}-hexane such as glues (Gonzalez and Downey 1972, Goto et al. 1974, Korobkin et al. 1975, Means et al. 1976, Oh and Kim 1976, Towfighi et al. 1976, King et al. 1985b, Dittmer et al. 1993, Takeuchi 1993), gasoline (Gallassi et al. 1980, Hall et al. 1986), and naptha (Tenenbein et al. 1984). Both \textit{n}-hexane and MBK (Menkes 1976) are metabolized to the same neurotoxin, 2,5-hexanedione, and produce a peripheral neuropathy. 2,5-Hexanedione is responsible for most, if not all, of the neurotoxic effects of exposure to \textit{n}-hexane or MBK (Spencer et al. 1980, Graham et al. 1982). MEK alone produces neither clinical nor pathological evidence of a peripheral neuropathy in experimental animals (Spencer et al. 1980); however, it acts synergistically with MBK or \textit{n}-hexane in experimental animals and probably in humans (Saída et al. 1976, Altenkirch et al. 1982, Ichihara et al. 1998). This potentiation of toxicity of one compound (MBK or \textit{n}-hexane) by an otherwise nontoxic compound (MEK) underscores the difficulty in sorting out toxic effects of individual solvents contained in a mixture.

Clinically and pathologically, the neuropathy occurring with \textit{n}-hexane or MBK is that of a distal axonopathy (Schaumburg and Spencer 1976). The clinical syndrome is an initially painless sensorimotor polyneuropathy, which begins after chronic exposure; weight loss may be an early symptom. Sensory and motor disturbances are noted initially in the hands and feet, and sensory loss involves primarily small fiber sensation (i.e., light touch, pin prick, temperature) with relative sparing of large fiber sensation (i.e., position and vibration). Electrophysiological studies reveal an axonal polyneuropathy and pathologically multifocal axonal degeneration, multiple axonal swellings, and neurofilamentous accumulation at paranodal areas (Spencer et al. 1975). Overlying the axonal swellings, thinning of the myelin sheath occurs. These findings are typical of a distal axonopathy or dying-back neuropathy described in relation to other toxic and metabolic causes of peripheral neuropathy.

Prognosis for recovery correlates directly with the intensity and duration of the toxic exposure and the severity of the neuropathy. Residual neuropathy is seen only in the most severely affected individuals with motor as well as sensory involvement, some of whom still continue to inhale despite warnings of further debilitation.

**Nonnervous System Toxicity of Inhalant Abuse**

Most of the known adverse clinical effects of inhalant abuse relate to its effects on the nervous system. There are, however, other significant adverse effects on other organ systems including the kidney, liver, lung, heart, and hematopoietic systems.

**Renal Toxicity**

This dysfunction, which may rapidly reappear in individuals who return to their habit after release from the hospital, is characterized by hyperchloremic metabolic acidosis, hypokalemia, hypocalcemia, and other electrolyte imbalances. Solvents usually cause a unique distal-type tubular acidosis, but proximal tubules (Al-Ghamdi et al. 2003) are also affected (the distal tubule is responsible for the known electrolyte and metabolic imbalance; the proximal type is responsible for the wasting of amino acids and other proteins). These subjects often have associated gastrointestinal involvement, including nausea, vomiting, and severe abdominal cramps. On the basis of these reports, renal dysfunction appears to be one of the most common toxic effects noted for solvent abusers. Although this renal damage is usually reversible, other organs, particularly brain, are the target of repetitive acidosis and any depletion of important amino acids. This may be the basis for some of the observed neurological deficits (Yamamoto et al. 1992).

Of all the solvents, toluene is most often correlated with this disease (Al-Ghamdi et al. 2003); however, other solvents, including chlorinated hydrocarbons, are frequently the basis for clinical syndromes.
for renal disease in these populations. Further animal studies are necessary to clarify specific solvent toxicities similar to those associated with nephrotic changes after exposure to halogenated hydrocarbons (Kimbrough et al. 1985, Lock 1989, 2006) and petroleum hydrocarbons (Short et al. 1987).

Clinicians especially need to be alert for pregnant women who abuse these solvents. Not only do they present to the clinic with renal tubular acidosis, but the fetuses may also be affected (Goodwin 1988, Lindemann 1991, Wilkins-Haug 1997). This condition places the mother at risk for hypokalemia and associated cardiac dysrhythmias and rhabdomyolysis (Wilkins-Haug 1997). Preterm labor therapy (β-mimetics and intravenous fluids) exacerbated the maternal and fetal problems. Fatty livers may also be observed in these pregnant subjects (Paraf et al. 1993). Treatment for their metabolic imbalance needs immediate attention.

Treatment
For pregnant as well as other patients, electrolyte repletion usually restores the kidney function and eliminates the muscle spasms even in the more severely affected patients in a few days. Correction of salt and electrolyte imbalance, including potassium, calcium, magnesium, phosphate, and bicarbonate (Davidman and Schmitz 1988, Wilkins-Haug and Gabow 1991), is important and may be considered in the treatment of solvent abusers for muscle fatigue even in the absence of more severe kidney disorders. Caution about the use of bicarbonate early in the treatment of these subjects has been discussed by Lavoie and coworkers (1987).

Pulmonary Toxicity
Solvents do irritate the lungs; however, few pulmonary problems have been reported (Devathanas et al. 1984). In two studies, mild pulmonary hypertension, acute respiratory distress, increased airway resistance and residual volume, and restricted ventilation were noted. Increased airway resistance or residual volume may be more clearly noted after an exercise challenge (Schikler et al. 1984, Reyes de la 1987). An increase in the frequency of respiratory (viral) illnesses, often noted in clinical reports, may be related to solvent exposure. In Australia (Currie et al. 1994), aspiration pneumonia was noted as a major cause of death in aboriginal sniffer. In sniffers in the US, aspiration pneumonia has not been a major cause of death. How to generalize the impact of dual exposure to solvent and infection is uncertain, but animal studies have measured decreased pulmonary bactericidal activity after exposure to solvents (e.g., dichloroethylene) (Sherwood et al. 1987). Animal studies have also measured pulmonary librosis in mice after solvent (TCE) (Forkert and Forkert 1994) exposure. A recent outbreak of respiratory illnesses has been associated with the leather treatment process where specific fluorocarbon aerosolized sprays are used (Hubbs et al. 1997).

Any pulmonary change may not be detected early on; it also may be enhanced by the other substances volatilized along with the solvent (e.g., polystyrenes, tars), utilized by the subject (e.g., tobacco and marijuana), or related to other conditions (Cartwright et al. 1983).

Cardiotoxicity
One of the most common causes of solvent-induced deaths is cardiac arrhythmia, especially ventricular fibrillation and cardiac arrest (Wright and Strobl 1984, King et al. 1985a, Boon 1987, Cunningham et al. 1987, McLeod et al. 1987, Zakhari and Salem 1991, Ong et al. 1988, Bowen et al. 1999, Avella et al. 2006). Bass (1970) reported deaths related to fluorocarbons; fluorocarbons were also demonstrated to cause arrhythmias in animals (Taylor and Harris 1970). Fluorocarbon propellants have mostly been replaced by butanes and propane. However, similar arrhythmias were observed after the abuse of these newly designed aerosols (with butanes etc.), lighter gases, and cooking gases (Bass 1984, Siegel and Wason 1990, Roberts et al. 1990, Sugie et al. 2004, Pfeiffer et al. 2006). Chenoweth (1977) has shown that butane, hexane, heptanes, gasoline, some anesthetics, and toluene also produce these arrhythmias. Cruz and colleagues (2003) have recently related some of these actions to altered sodium currents. Although less common, sniffing glue (Cunningham et al. 1987, Knight et al. 1991, Wernisch et al. 1991) and TCE-containing stain removers (Wright and Strobl 1984, Hantson et al. 1990) have been linked to arrhythmias, myocarditis, and cardiac arrest. Organic nitrates have also been reported to produce bradycardia (Rosoff and Cohen 1986).

When arrhythmias are observed, antiarrhythmic therapy should be used (McLeod et al. 1987). Recovery from cardiopulmonary arrest is not common; however, a successful resuscitation from fluorocarbon overexposure has been reported (Brilliand and Grillo 1993). Cardiopulmonary resuscitation (mouth to mouth) followed by defibrillation within 7 minutes was the primary emergency treatment. Exercise and epinephrine exacerbate these cardiotoxicities.

Hematopoietic Toxicity
Of great concern are the incidences of neoplasm in solvent abusers. A common solvent, benzene, has long been identified as causing aplastic anemia and acute myelocytic leukemia (Austin et al. 1988, Yardley-Jones et al. 1991). Benzene is present in thinners, varnish removers and other solvents, and gasoline, which may lead to various neoplasms (Lauwerys et al. 1985, Knight et al. 1991). Based on the release of the nitrite ion in blood after the administration of organic nitrates, the ability to produce nitroamines has fueled the speculation that nitrates are carcinogenic (Osterloh and Goldfield 1984, Yamamoto et al. 1987, Dunkel et al. 1989).

Most hematological changes can be overcome by the regenerative nature of red blood cells. Carbon monoxide, at high levels, produces cerebral hypoxia, which may subsequently have permanent neurological sequelae; it also produces carboxyhemoglobin. This occurs with exposure to a common solvent, methylene chloride (Horowitz 1986, Chang et al. 1999), as well as to cigarette smoke. The acute elevation of carboxyhemoglobin after exposure to methylene chloride has been studied in controlled experiments in humans (Stewart et al. 1972, Gamberale et al. 1975, Winneke 1981). The elevation is a result of the metabolism of the solvent methylene chloride to carbon monoxide (Stewart and Fisher 1972, Kubic et al. 1974, Ratney et al. 1974, Astrand et al. 1975), and therefore, the hypoxic effect of carbon monoxide as well as its narcotic actions must be taken into account in considering the actions of methylene chloride. The levels of carboxyhemoglobin may become
sufficiently high to cause brain damage (Barrowcliff and Knell 1979) or death (Manno et al. 1989).

One group of substances—the organic nitrites—produces a different hematological change, the formation of methemoglobin and hemolytic anemia (Wason et al. 1980, Brandes et al. 1989). This group of substances includes the volatile liquids amyl, butyl, isopropyl, and cyclohexyl organic nitrites. These drugs are not the typical solvents of most solvent abusers. A study could not correlate changes in regional blood flow with any psychological measures or somatic changes (Mathew et al. 1989b); also, isoamyl nitrite did not substitute for barbiturates as a reinforcing agent as do toluene and other solvents (Rees et al. 1987). These studies do not offer any explanation for why individuals become dependent on nitrites. However, the finding by Mathew and colleagues (1989b) that nitrites reduce anger, fatigue, and depression may offer a clue.

The nitrites are not usually considered toxic during inhalation because of syncope (fainting), and overdose is unlikely. However, Guss and coworkers (1985) noted a dangerously high methemoglobin level in a normal subject who had used isobutyl nitrite. Methemoglobinemia is the major identified toxicity of organic nitrites and is the cause of several deaths (Wood and Cox 1981). However, there is a specific treatment for nitrite overdose. The high and slowly reversible reduction of methemoglobin can be enhanced by the use of methylene blue (Smith et al. 1980).

Organic nitrites have also been reported to alter immune function as measured by direct lymphocytic actions (Soderberg and Barnett 1995) or in whole-animal studies (Gaworski et al. 1992). These effects are of special concern in the development of acquired immunodefi ciency syndrome (AIDS). Haverkos and associates (1994) reviewed the possible link between the development of Kapo’s sarcoma and high amyl or butyl nitrite use. Seage and colleagues (1992); however, proposed that the link is related to enhancement of the accessibility of the human immunodeficiency virus.

Early studies did not show major effects of organic nitrites on isolated immune or bacterial cells (Lewis and Lynch 1988, Jacobs et al. 1983); however, studies by Soderberg’s group (Soderberg and Barnett 1995) showed that isobutyl nitrite inhalation resulted in dissolution of T-dependent immune mechanisms, including the induction of antibodies and cytotoxic T cells and of macrophage tumoricidal activity. This loss of immunity depended on habitual exposure and lasted for up to 5–7 days after exposures were terminated. The infant apparently produces this immunotoxicity by altering accessory cell functions, including diminished production of IL-1B in macrophage (Soderberg et al. 2004).

**Neonatal Syndrome**

Newborns of mothers who chronically abuse solvents (Hersh 1989, Hersh et al. 1985, Goodwin 1988, Donald et al. 1991, Wilkins-Haug 1997) often present with abnormal growth similar to that described for the fetal alcohol syndrome. The mothers inhaled paint thinner and paint sprays and some also drank various quantities of alcohol. Thus, toluene may augment the fetal alcohol syndrome when alcohol is also consumed. It is also worth noting that the mothers of the infants in one (Hersh 1989) study showed ataxia, mild tremors, and slurred speech, and the mothers in the other studies presented with severe renal tubular acidosis. Newborns of these women showed growth retardation and some dysmorphic features including microcephaly and also distal aci-

dosis and aminoaciduria (Wilkins-Haug 1997, Lindemann 1991). Some of these abnormalities were also observed in rodents exposed to toluene (Donald et al. 1991); however, the extent and severity of the effects are unclear. That solvents produce a “fetal syndrome” has been more comprehensively evaluated in a study of pregnant women who used toluene-based-solvents and/or alcohol (Tenenbein [2005], personal communication). In this study, only the babies of mothers who abused alcohol were observed to have a “fetal alcohol-t syndrome.” However, some of the newborns of solvent abusers presented with renal acidosis.

Nitrous oxide has been shown to produce some “major visceral and minor skeletal (fetal) abnormalities” (Mazze et al. 1988). Also, animal studies demonstrated fetal toxiciti-
cies of the liver caused by carbon tetrachloride (Cagen and Klaassen 1979) and malformations by chloroform (Murray et al. 1979). It is, thus, important that pregnant women not be exposed to very much of these substances. It is encouraging to know that a critical prospective study of female workers exposed to low levels of solvent showed no more fetal abnormalities than in the carefully matched control subjects (Eskenazi et al. 1988). This does not, however, diminish the need for pregnant women to avoid exposure to most solvents, especially at the high levels incurred through deliberate abuse.

**Treatment**

Individuals need different treatments based on the severity of the dependence and medical complications. Primary care physicians should address the medical issues identified earlier as well as other medical concerns before dealing with the dependence on solvents and other drugs. During this period, sedatives, neuroleptics, and other forms of phar-

macotherapy are not useful in the treatment of inhalant abusers and should be avoided in most cases as they are likely to exacerbate the depressed state and may complicate the problem of cardiac arrhythmia, especially in the acute intoxication stage.

Given the wide range of inhalants that are used, there are likely to be subpatterns of users (based on age and geographical regions, see Howard et al. 2007) for which treatment approaches might differ. Unfortunately the litera-
ture contains very little information about these categories. It is known that many users will gravitate toward certain products (e.g., toluene, nitrous oxide); these people may share common psychosocial backgrounds. Younger users may be more likely to use toluene-containing products whereas adults might prefer nitrous oxide (Wu and Ring-

walt 2006). Another pattern might exist for professionals in the medical field who abuse anesthetics. Clearly, they would differ in multiple ways from abusers who prefer toluene, for instance. Until a better characterization of types of inhalant users is available, treatment planning would benefit from a complete history of inhalant use and a detailed psychosocial profile of individual users. Also, treatment of inhalant abuse at some drug treatment centers is often integrated with treatment for other types of drug use with no unique approaches identified for those with a primary inhalant disorder (Sakai et al. 2006); in contrast many heavily inhalant-dependent individuals (with inhalants as the major if not only drug
abuse disorder) are treated in an inhalant-unique treatment environment (Dinwiddie et al. 1987, Reidel et al. 1995).

Data on evidence-based treatment approaches for inhalant problems is extremely scarce and there is no accepted treatment protocol. Dinwiddie et al. (1987) reported a 100% relapse rate for young adult heavy-inhalant users 6 months after treatment. Sakai et al. (2006) found a reduction in inhalant use in a 2-year follow-up of adolescents admitted to a behavior modification, inpatient treatment program. Reidel et al. 1995 designed a program specifically for inhalant using adolescents employing education, neurocognitive retraining and cultural practices in a 90–120 day inpatient program. Six-month follow-up data revealed significant improvement in neurocognitive functioning and educational achievement and reductions in inhalant use. Given the design of the follow-up study it was not possible to tell what elements of the intervention were effective in producing the gains they found.

Most of what has been written on inhalant treatment derives from the nature of inhalants themselves and observations from those who have attempted to provide treatment. It is generally agreed that inhalants induce neurocognitive impairment that interferes with the usual treatment approaches (e.g., psychotherapy and educational interventions in the early stages of treatment). Since inhalants are lipophilic, clearance from the body is very slow and the neurocognitive effects are longer lasting than may be found for other drugs. While there is little empirical evidence regarding the slope of the clearance curve, there is agreement that detoxification for heavy inhalant users requires an extended period and may take up to 1 month, and perhaps even longer depending on the history of use (Fornazzari 1988, Jumper-Thurman and Beauvais 1997). The recommendation for this period of time is to focus on basic life skills, hygiene, and dietary issues with minimal attention to therapeutic interventions. Neurocognitive testing may help in tracking the course of detoxification although there is question as to the utility of this during acute intoxication. Initial therapeutic interventions should be brief (15–20 minutes) and can be gradually extended depending on the cognitive clarity of the patient.

The evidence cited above for higher levels of psychiatric disorders, neurocognitive deficits and social dysfunction likely account for the intractableness inhalant users show toward treatment (Evren et al. 2006; Jumper-Thurman and Beauvais 1992). Further, these characteristics provide a distinctive profile that sets inhalant users sufficiently apart from other drug users. It is recommended that patients for whom inhalants are the primary drug of abuse be treated in programs specifically designed for inhalant abuse. Patients with a long history of abuse, and considering the lengthy detoxification period, usually require inpatient treatment. These findings also make it essential that screening for comorbid conditions be conducted before treatment planning commences. In particular, it is important to obtain a detailed history of use of other drugs of abuse, including alcohol, so that these conditions can also be addressed. It is not uncommon for patients to prefer drugs other than inhalants but will use inhalants when they are unable to afford other drugs. If the full range of comorbid conditions are not addressed, treatment is likely to fail.

A consequence of the manifold problems that inhalant users present is the need for increased intensity and length of treatment; the usual 14- to 30-day inpatient treatment is rarely sufficient to address the full range of issues. Some clinics report that a 6–12 month treatment regimen is required. Multiple resources are needed to attend to the various physical, neurological, social, and psychiatric problems that may be present. For younger patients it is important to involve family members in the process since family relationships have often deteriorated. (Dell et al. 2005, Howard and Jensn 1999). Given the high rates of relapse that have been observed among inhalant users, attention to follow-up care is essential (Reidel et al. 1995). Resources need to be identified in the community and close contact and coordination need to be maintained to reintegrate the patient back into a supportive environment. During treatment it is critical to restrict access to inhalable substances. This may be difficult given the ubiquity of inhalants. In inpatient settings maintenance and cleaning supplies should be carefully controlled. Drug screening would be useful in monitoring inhalant abusers. Routine urine screening for hippuric acid (the major metabolite of toluene) performed two or three times weekly can detect the high level of exposure to toluene commonly seen in inhalant abusers. More frequently performed expired breath analysis for toluene or other abused compounds is also available. As alcohol is a common secondary drug of abuse among inhalant abusers, alcohol abuse should be monitored and considered in the approach to treatment.

Taking a more global view of the treatment process, the following areas require consideration:

- Culture
- Family structure
- Living environment
- Peer interactions
- Individual’s ability to learn and adapt
- Establishment of self-image
- Individual attitudes and behavioral characteristics
- Building basic life skills
- Social bonding

Clinical Vignette

A 15-year-old Native American boy was brought to the emergency department by the police after being arrested for vandalism and stealing. He was found with about a dozen butane cigarette lighters and some whippet canisters that he had stolen. When taken into custody, he was staggering and appeared confused. At the emergency department, he had a “gasoline-like” smell on his breath and was disoriented to time. On a brief neurological examination, he had nystagmus and cerebellar ataxia (wide-based gait, poor finger-to-nose pointing). A urine toxicology test for hippuric acid was positive. Because of his neurological findings an MRI scan was obtained. The scan showed multifocal white matter hypodensities consistent with demyelinating axonal degeneration. He was admitted to the hospital for observation and released 3 days later after a medical history could be obtained from him. He had run away from his home reservation a year earlier and had been abusing alcohol and a wide range of inhalants including butane, nitrous oxide, and toluene (glue sniffing) on an almost daily basis. The diagnosis was inhalant use disorder, dependence.

Clinical Vignette

A 16-year-old male presented due to altered mental status. According to the history provided by his family, 1 day before admission he was observed to be confused and lethargic and also reported seeing hallucinations of spiders. These changes worsened with the patient becoming noncommunicative and intermittently agitated overnight. On examination, he was nonverbal, rarely nodded yes or no, and intermittently followed only simple commands. He had masked facies, appeared apathetic, and sat motionless. Examination of cranial nerves, motor strength, tone, and reflexes were normal. Coordination testing was difficult; however, he seemed to have a mild degree of ataxia in both upper extremities. His gait was slow but otherwise normal. Sensory testing was limited owing to his mental status, but light touch and pain appeared intact. Routine urine toxicology was negative for amphetamines, cocaine, barbiturates, benzodiazepines, and opiates; this toxicology screen did not include testing for butane or other aromatic compounds that are abused via inhalation. Further history by a sibling revealed that the patient had inhaled a can of butane 2 days before his admission. This can, brought to the hospital by the parents, was a 300-mL empty can of butane lighter fluid. Laboratory confirmation of the butane exposure with gas chromatography was deemed futile as the urine collected was well over 24 hours postexposure. Laboratory studies did not indicate signs of infection, hepatic or renal dysfunction. An electroencephalogram recorded 2 days after admission demonstrated diffuse background slowing, intermittent bilateral frontal delta waves, and an abnormal arousal response pattern consistent with a toxic or metabolic encephalopathy. Magnetic resonance imaging demonstrated markedly abnormal increased signal in the thalami bilaterally on fluid-attenuated inversion recovery and other T2-weighted sequences. Signal abnormalities were also observed but to a lesser degree of severity in both insulae and right cerebellum. Diffusion-weighted imaging documented increased intensity in the thalami; however, the apparent diffusion coefficient maps did not indicate restricted diffusion consistent with infarction. Rather, the increased apparent diffusion coefficient values were indicative of edema and the diffusion-weighted imaging appearance that of "T2 shine through" of the edematous tissue. The neuroradiologic impression was that the imaging findings were consistent with a metabolic or toxic etiology, given the symmetry of the abnormalities. The patient remained hospitalized on the rehabilitation service, 3 months after admission, manifesting little change in his clinical symptoms. When he was last evaluated by the neurology service, he continued to exhibit a profound mutism and apathy.

Clinical Vignette

A 30-year-old male, ex-convict, came to counseling concerning a persistent "tingling" in his hands. He had consulted several physicians who could provide no plausible explanation and he was wondering if it was "something in his head." The man had a history of heavy use of multiple drugs of abuse, including inhalants. He maintained that he had been clean for several years. When queried about the types of inhalants used he produced an extensive list of substances but said he couldn't remember everything that he probably used. He said that of all the drugs he had used he preferred inhalants. When asked why he responded with: “You know the feeling of euphoria you feel when you are at the top of a roller coaster and are just starting to go down? That’s how it is with inhalants, you can keep snifffing just enough at a time to keep that feeling going for a long time. It is such a rush and I have to be careful since I continue to have strong urges to go back to using.” The counselor explained that the tingling sensation may well be the result of his use of an inhalant that contained n-hexane and that it may persist for some time. If he continued to be concerned about it he was encouraged to see a neurologist.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

The ICD-10 and DSM-IV-TR criteria sets for Inhalant Intoxication are nearly equivalent (except that DSM-IV-TR lists additional symptoms).

A Tribute to Dr. Neil Rosenberg

It was a tragic loss of Dr. Neil Rosenberg, an active neurologist, shortly after the publication of the second edition of this chapter. His findings, thoughts, and guidance are still a major part of this chapter. He was concerned about young people causing dementia prematurely not only through the voluntary overexposure of themselves to solvents but also through the use of other substances such as methamphetamine. He was a pioneer in the field of defining neurologic manifestations of solvent abuse and with his wife, Cathy, founded the International Institute on Inhalant Abuse. He devoted his energies through academic groups, including NIH and the American Academy of Neurology. More humbly he traveled throughout the United States and Central and South America, educating people about the dangers of inhaling chemicals and provided extensive humanitarian assistance to poor people in Peru and other countries in the Latin Americas as well as Native Americans in the northern hemisphere, always with the prime goal of diminishing solvent- and other drug-dependent activities.

Wu LT and Howard MO. (2006a) Psychiatric disorders in inhalant users: Results from The National Epidemiologic Survey on Alcohol and Related Conditions Drug and Alcohol Dependence Nov 25; [Epub]  

Tobacco use is common throughout the world with there being about 1.25 billion smokers of which 1 billion are male and only 50 million live in the US (Lando et al. 2005, Warren et al. 2006). Even though only 4% of the world’s smokers are from the US, nicotine dependence is the most common substance use disorder (SUD) in the US with 20.6% of the adult US population smoking cigarettes (Centers for Disease Control and Prevention 2006). Tobacco-caused diseases are the second most common cause of death in the world, including 5 million in 2005 and an estimate of 10 million in 2020 (Warren et al. 2006, The World Health Report 2002). Tobacco use and nicotine dependence has serious health consequences for the user, family members, and others who breathe environmental tobacco smoke or are exposed during pregnancy. Tobacco use and nicotine dependence increases morbidity and mortality. A large proportion of individuals with a current Axis I disorders (mental illness and/or other SUDs) are also nicotine dependent. In the US, the overall reduction in smoking rates in the general population has not been matched by proportional reductions amongst individuals with psychiatric disorders (Ziedonis and Williams 2003). As a result, about 44% of all the cigarettes consumed in the US are by individuals with psychiatric disorders (Lasser et al. 2000). The high rates of psychiatric disorders amongst smokers are common throughout the world (deLeon and Diaz 2005).

**Diagnosis**

Nicotine dependence was first included as a SUD in the *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition (DSM-III) in 1980 (American Psychiatric Association 1980). The nicotine withdrawal syndrome occurring after abstinence was also first classified as a disorder in DSM-III (American Psychiatric Association 1980). Of note, the DSM distinguishes nicotine from other substances by not including a diagnosis of nicotine abuse because most individuals transit quickly and directly from use to dependence (meeting criteria of tolerance and withdrawal).

**Definition and Diagnostic Features**

The definition of Nicotine Dependence is similar to other SUDs and is listed in the Table of Diagnostic Criteria. In the DSM-IV-TR (American Psychiatric Association 1994), a specifier is used to designate the presence or absence of physiological dependence, depending on whether tolerance or withdrawal is present or whether both are absent. Further specifiers can be used to denote course (e.g., early full remission or sustained partial remission). Diagnostic features include the nicotine withdrawal syndrome and level of dependence severity.

The DSM-IV-TR nicotine withdrawal syndrome describes a characteristic set of symptoms that develops after abrupt cessation or a reduction in the use of nicotine products after at least several weeks of daily use and is accompanied by four of the following signs and symptoms: (1) dysphoria or depressed mood, (2) insomnia, (3) irritability, frustration, or anger, (4) anxiety, (5) difficulty concentrating, (6) restlessness or impatience, (7) decreased heart rate, and (8) increased appetite or weight gain (American Psychiatric Association 1994). The withdrawal symptoms must also cause clinically significant distress or impairment in social, occupational, or other important areas of functioning and must not be secondary to a general medical condition or be accounted for by another mental disorder. Other symptoms that may be associated with nicotine withdrawal include craving for nicotine, a factor thought to be significant in relapse; a desire for sweets, and impaired performance on tasks requiring vigilance. The World Health Organization's
ICD-10 criteria list also has craving, malaise, increased cough, and mouth ulceration and does not include the DSM decreased heart rate item.

To some extent, the degree of physiological dependence predicts severity of the withdrawal syndrome and difficulty in stopping smoking. The Fagerström Test for Nicotine Dependence (Heatherton et al. 1991) was developed to assess the degree of physical dependence on nicotine. Its two primary measures are number of cigarettes smoked per day and time in the morning until the first cigarette (see Section on “Assessment”). These two primary items are often used in isolation and called the Heaviness of Smoking Index (HSI) (Heatherton et al. 1989). A score of six or higher on the Fagerström Test for Nicotine Dependence (FTND) is indicative of higher severity of nicotine dependence (Fagerström et al. 1992), but does not constitute a definitive diagnosis. In addition to frank symptoms, other objective biological and physiological changes are associated with nicotine withdrawal, such as generalized slowing of electroencephalographic activity, decreases in catecholamine and cortisol levels, changes in rapid eye movement, impairment on neuropsychological testing, and decreased metabolic rate.

(5) A great deal of time spent in activities necessary to obtain the substance, in use of the substance, or in recovery from its effects, for example, chain smokers who spend a good deal of the day in smoking activity or smokers with workplace smoking restrictions who interrupt their work repeatedly for cigarette “breaks”

(6) Important social occupational, or recreational activities given up or reduced because of substance use, for example, some smokers may have had to change jobs because of an inability to accommodate their smoking to workplace restrictions, although this would be uncommon

(7) Continued use despite having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by nicotine use, for example, continued smoking after the occurrence of a myocardial infarction or in the face of marital conflict related to the person’s smoking

### DSM-IV-TR Criteria

**Nicotine Dependence**

A pattern of nicotine use, leading to clinically significant impairment or distress, as manifested by at least three of seven criteria occurring at some time during a 12-month period:

1. **Tolerance**
   - Absence of nausea, dizziness, and other characteristic symptoms of nicotine despite using substantial amounts or
   - A diminished effect with continued use of the same amount of nicotine

2. **Withdrawal**
   - Presence of a characteristic withdrawal syndrome (see nicotine withdrawal) or
   - The use of the substance or related substances to relieve or avoid withdrawal symptoms, for example, smoking a cigarette immediately upon waking in the morning after a night of abstinence or immediately smoking a cigarette after disembarking from a long plane flight in order to relieve withdrawal symptoms

3. Use of nicotine in larger amounts or over a longer period than was intended, for example, using up a package of cigarettes faster than originally intended

4. Persistent desire or unsuccessful efforts to cut down or control nicotine use, for example, most smokers desire to stop smoking but numerous attempts are often required before successful cessation is achieved

5. A great deal of time spent in activities necessary to obtain the substance, in use of the substance, or in recovery from its effects, for example, chain smokers who spend a good deal of the day in smoking activity or smokers with workplace smoking restrictions who interrupt their work repeatedly for cigarette “breaks”

6. Important social occupational, or recreational activities given up or reduced because of substance use, for example, some smokers may have had to change jobs because of an inability to accommodate their smoking to workplace restrictions, although this would be uncommon

7. Continued use despite having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by nicotine use, for example, continued smoking after the occurrence of a myocardial infarction or in the face of marital conflict related to the person’s smoking

---

### Table 62–1 Assessing Nicotine Use and Nicotine Dependence

| Current and past patterns of tobacco use (include multiple sources of nicotine) |
| Objective measures: breath CO level or cotinine level (saliva, blood, urine) |
| Assess prior quit attempts (number and what happened in each attempt) |
| Why quit? How long abstinent? Why relapsed? |
| What treatment was used (how used and for how long) |
| Assess withdrawal symptoms and dependence criteria |
| Psychiatric and other substance use history |
| Medical conditions Their common triggers (car, people, moods, home, phone calls, meals, etc.) |
| Perceived barriers against and supports for treatment success Preference for treatment strategy |
dependence. It should be noted, however, that because some items assume that the smoker has primary control over their environment (e.g., the number of minutes after waking until first cigarette) these measures may be less relevant to those with serious mental illness or adolescents for whom the smoking environment is at least partially under the control of others (Steinberg et al. 2005).

In addition, the amount of tobacco usage can be assessed through cotinine levels or carbon monoxide (CO) levels. Cotinine levels can be obtained from the urine, blood, or saliva to assess the amount of nicotine ingested. Cotinine is a primary metabolite of nicotine and remains in the body for several weeks. Despite the advantage of this longer opportunity for detecting nicotine usage, the cotinine tests are costly and may require several days for a lab to report the results. In contrast, the expired-air test for a CO level is less costly and can be obtained within a min by any clinician with a CO meter. The CO meter is useful at intake and to monitor for relapse. Higher cotinine and CO levels are associated with a higher number of cigarettes per day and also severity of nicotine withdrawal. For the 20-cigarette-per-day smoker, expired-air CO levels are typically in the 10−30 parts per million (ppm) range and cotinine levels 250 to 300 ng/mL range.

A history of prior cessation attempts should include the nature of prior treatments, length of abstinence, timing of relapse, and factors specifically related to relapse (e.g., environmental or interpersonal triggers). An assessment should be made of the person’s reasons for quitting, his or her motivation and commitment and self-efficacy (perceived ability to quit). The individual’s stage of readiness (motivation) for stopping smoking is also important. One common model for conceptualizing motivation describes five stages: precontemplation, contemplation, preparation, action, and maintenance stages (Prochaska 1983). Clinicians determine whether the person is not yet seriously considering stopping smoking (precontemplation), is considering attempting to quit but not for several months (contemplation), is seriously considering quitting in the next month and has begun to think about the necessary steps to stop smoking (preparation), or is actually attempting to stop smoking (action) (Prochaska 1983). It is also important to assess the smoker’s knowledge about smoking and nicotine dependence because deficits in knowledge and information can have a deleterious effect on smoking cessation attempts.

Assessing prior treatments includes assessing prior use of medications and psychosocial treatments. There are now seven Food and Drug Administration (FDA)-approved medications for nicotine dependence treatment, including five nicotine replacement therapies (NRT) (such as the patch, gum, spray, inhaler, and lozenge) and two non-nicotine pills bupropion (Zyban) and varenicline (Chantix). Non-FDA approved medications with some evidence supporting their use include nortriptyline and clonidine (Work Group on Substance Use Disorders, et al. 2006). Assessing about prior medication use includes asking about what dose of medications and how long it was taken; any side effects that developed; and how the patient actually took the medication (especially relevant for NRT). For example, the patient may report taking off the NRT patch prior to a shower and then replacing the same patch, rendering it ineffective. Prior psychosocial treatments might include group or individual treatment, American Lung Association and other community support groups, hypnotherapy, acupuncture, or Nicotine Anonymous. Understanding how long a patient was engaged in these approaches and whether the medications and psychosocial treatments were combined can be helpful in creating a new treatment plan. Evaluating potential triggers for tobacco use is important, including social context, time of day, and relationship to other activities, moods, people, and places. Triggers might include driving the car, speaking on the phone, meals, etc. In addition, the first two weeks of abstinence are a particularly vulnerable time period for withdrawal symptoms to be a trigger for use. A history of specific withdrawal symptoms and their severity and duration is critical, as is an assessment of the smoker’s social and environmental contexts, for example, whether other household members smoke, and available family and social supports.

Assessment of the psychiatric history is also important. Numerous studies have shown the significance of current and past depression in relation to smoking, as well as the increased prevalence rates of cigarette smoking in patients with a variety of psychiatric disorders, such as schizophrenia, alcohol and substance abuse (see Section on “Comorbidity Patterns”). The presence of these comorbid disorders may also make successful smoking cessation less likely (see section on special features influencing treatment), especially if undiagnosed and untreated.

Assessing the patient for a history of current alcohol or other substance abuse is also important, as the prevalence of smoking in persons with alcohol dependence as well as in other substance abusers is much higher than in the general population. It may also be more difficult for individuals with current or prior substance abuse or dependence to stop smoking, as there is evidence that persons with alcohol dependence and other substance abusers start smoking earlier and are more physiologically dependent on nicotine (Hughes 1993b). In addition, the use of alcohol or other substances may be intimately linked to smoking cigarettes and can serve as a strong trigger for craving and ultimate relapse.

A careful medical history should also be obtained. The presence of significant tobacco-related medical illness can sometimes serve as crucial leverage to help motivate the individual to attempt cessation. Current medications and medical conditions may also be important considerations in determining the approach to cessation, especially with regard to pharmacotherapy. For example, a history of seizures or an eating disorder is usually a contraindication to the use of bupropion/Zyban (nonnicotine pill medication). The individual should be assessed for pulmonary symptoms and signs (cough), and if there is a long history of significant nicotine use, pulmonary function tests should be considered. The presence of significant cardiovascular disease, especially a history of recent myocardial infarction, is especially relevant to planning psychopharmacological interventions. If the individual is already taking a psychiatric medication, consider it important to realize that quitting smoking may result in an increase in medication blood levels and side effects.

Epidemiology
Tobacco use is very common throughout the world and there is great concern about the increase in tobacco-caused
Comorbidity Patterns

Nicotine dependence and smoking are two to three times more common in individuals with psychiatric and other SUDs than in the general population (Hughes et al. 1986, Glassman 1993, Dierker et al. 2002). The high rates of psychiatric disorders amongst smokers are common throughout the world (deLeon and Diaz 2005, Lasser et al. 2004). Smoking-related illnesses are the primary cause of death among those in recovery from other substances. It is estimated that 55–90% of individuals with psychiatric disorders smoke versus the 20.6% of the general population. The prevalence of smoking is especially high in patients with schizophrenia (70–90%), generalized anxiety disorder (46%), alcohol abuse or dependence (43.5%), drug abuse or dependence (49%), and major depression (36.6%). Conversely, there is also evidence that affective, anxiety, and SUD may be more common in individuals who smoke than in those who do not or in those who have never smoked (Glassman 1993). Finally, there is evidence to suggest that in one study up to 75% of smokers with a history of MDD developed depressed mood during the first week of withdrawal versus only 30% of those with no depressive history, and that the withdrawal syndrome may be more severe in smokers with a history of depression (Covey et al. 1990). The presence of depressive symptoms during withdrawal is also associated with failed cessation attempts (West et al. 1989, Hughes 1992). Self-reported depressive symptoms during adolescence also predict later frequency and duration of smoking (Kandel and Davies 1986). Several studies suggest a genetic predisposition to both nicotine dependence and co-occurring depression (Carmelli et al. 1990, Kendler et al. 1993, Dierker et al. 2002, Glassman et al. 1990). It is interesting to note that a history of single-episode depression is not associated with reduced rates of smoking cessation, though a history of recurrent depression may be (Hitsman et al. 2003). ADHD decreases the age of onset of cigarette smoking and increases the overall risk for nicotine use in early adolescence (Millberger et al. 1997a, 1997c). Others have also found that adolescents with ADHD were three time more likely to smoke than adolescents without ADHD (Tercyak et al. 2002). Kollins et al. (2005) reported in a very large study including a cohort of 15, 197 eligible respondents between 15–22 years old that each reported inattention and hyperactivity/impulsivity symptom significantly increased the likelihood of regular smoking. There is also support for the idea that smoking may act as a gateway, increasing the risk for subsequent use of cannabis and other illicit drugs (Biederman et al. 2006). ADHD increases the risk for cigarette smoking and SUD) and is associated with greater SUD severity and chronicity (Wilens and Biederman 2006). A history of childhood ADHD is predictive of smoking cessation (Humfleet et al. 2005). Adult smokers with ADHD have more problems quitting than those without this condition (Pomerleau et al. 1995). The connection between ADHD and smoking is believed to be mediated by nicotine’s enhancement on attention and concentration. Abstinence from nicotine can increase symptoms of inattention and hyperactivity-impulsivity and these symptoms are predictive of relapse (Rukstalis et al. 2005).

There is no simple reason why so many psychiatric patients smoke. As with other addictive disorders, a
combination of complex biological and psychosocial factors is likely. Potential biological factors in this group include a greater likelihood of susceptibility to nicotine dependence, with persons experiencing a greater sense of reward from nicotine. Other possibilities include using nicotine to reduce the side effects of psychiatric medications, both as a stimulant to counter sedation as well as a dopamine modulator that can diminish neuroleptic-induced parkinsonism. Subjectively, patients report that using nicotine improves their cognitive functioning and reduces stress, although research data is mixed in this regard (West and Hack 1991). In patients with schizophrenia, an abnormality in P50 gating, which is believed to relate clinically to the ability to filter out distracting auditory stimuli, is temporarily reversed with nicotine. Social and behavioral factors are also important in understanding nicotine dependence, and psychiatric and addictive comorbidity. Smoking has been ignored and is part of the pervasive culture in most mental health and substance abuse treatment centers and residential facilities. This is beginning to change. Historically, smoking was often used as a behavioral reward in psychiatric inpatient units and continues to serve as a social connector for many psychiatric patients. Patients who are coping with persistent psychiatric symptoms and reduced social and occupational functioning report smoking to fill the voids of boredom and disappointment (Ziedonis et al. 1994, Hall et al. 1991, Anda et al. 1990).

Course
Nicotine dependence has been called a “pediatric disease” since most smokers started during adolescence. By the age of 18, 90% of those who will ever try a cigarette have done so, and age 18 years is the average age at which individuals become daily smokers. As with other SUD, the etiology of nicotine dependence is multifactorial and includes biological, psychological, and social factors, including genetic factors.

Nicotine is the primary psychoactive agent in tobacco smoke and smokeless tobacco and has powerful addictive properties (Benowitz 1988). As an indication of the addictive potential of this substance, one-third to one-half of all children and adolescents who smoke one cigarette progress to become habitual users. Nicotine is considered to be the “gateway drug” to the use of other substances (Henningfield et al. 1990, Lai et al. 2000).

The National Health Interview Survey found that 70% of smokers interviewed reported they wanted to quit smoking at some point in their lifetime, and about 33% of smokers try to quit each year. Only about 3% of quit attempts without formal treatment are successful, and in recent years about 30% of smokers who want to quit are seeking treatment—including only 5% who seek counseling services (Zhu et al. 2000). Outcomes for nicotine dependence treatment vary by the type of treatment and the intensity of treatment with specific reports ranging from about 15−45% 1-year abstinence rates following treatment. Cessation attempts result in high relapse rates, with the relapse curve for smoking cessation paralleling that for opiates. Most individuals relapse trying to quit without treatment relapse within the first 8 days (Hughes et al. 2003). Recent data examining the natural time course of nicotine withdrawal indicates that different withdrawal symptoms reach their “peak” intensity at different times and that all withdrawals symptoms return to baseline within 10 days (Shiffman et al. 2006).

Differential Diagnosis
Most tobacco users meet criteria for nicotine dependence; however, about 5% of tobacco smokers in the US are considered tobacco “chippers” and are not nicotine dependent. Chippers are occasional social smokers who may smoke up to five cigarettes in a day but do not smoke daily. They may smoke up to four days a week, however, they do not appear to suffer from nicotine withdrawal symptoms. Typically chippers use tobacco in a social context and not to “self-medicate.” There appears to be a genetic link with chippers coming from a family of chippers; individuals from families of smokers who are nicotine dependent may appear to be occasional users initially, however, they usually progress rapidly to be nicotine dependent. Alcohol use can be a trigger for chippers to increase their tobacco use. Although these individuals are not nicotine dependent, they are still at risk for tobacco caused diseases since there is no safe dose of tobacco use (Work Group on Substance Use Disorders, et al. 2006).

Differences in Developmental, Gender, and Cultural Presentation
Smoking is more common among white students (39.7%) than among Hispanic (34.0%) and black students (22.7%). The racial/ethnic differences are particularly striking among females; more than two times as many white females currently smoke (39.9%) as black females (17.4%), and almost five times as many white females are frequent smokers (20.1%) compared with black females (4.3%). Earlier data have shown high prevalence rates among American Indians and low prevalence rates among Asian-American and Pacific Islander youth, especially females. Smoking among black youth has shown the greatest increase since 1991, almost doubling from 12.6% in 1991 to 22.7% in 1997. Smoking was historically more common among men, but women are now almost as likely to smoke as are men; smoking among men has dropped, and women have caught up. This pattern is evident in several developed countries. In the developing world, sharp gender differences are still the norm. Even though prevalence has equalized, men still smoke more heavily than women. More than men, women report that they smoke in order to deal with stress and emotion. Despite their lighter smoking, women appear to be less successful at quitting smoking. Several avenues of research now indicate that men and women differ in their smoking behavior. For instance, women smoke fewer cigarettes per day, tend to use cigarettes with lower nicotine content, and do not inhale as deeply as men. However, it is unclear whether this is due to differences in sensitivity to nicotine or other factors that affect women differently, such as social factors or the sensory aspects of smoking.

Etiology and Pathophysiology

Genetic Factors
Family, adoption, and twin studies strongly suggest the role of genetic factors in cigarette smoking. Comparing twins reared together and apart showed that in men the regular tobacco use has both genetic and rearing-environmental factor accounting for 61% and 20%, respectively.
(Kendler et al. 2000). Another study looking at reared together monzygotic and dizygotic twins demonstrated that the liability for regular tobacco use breaks down as follows: 54% genetic, 24% familial-environmental and 20% individual-specific environmental risk factors (Sullivan and Kendler 1999). There is substantial overlap of the genetic factors predisposing to smoking initiation and the ones promoting the transition to nicotine dependence (Sullivan and Kendler 1999). The overall heritability of nicotine dependence is thought to be 60% (True et al. 1999, Kendler et al. 2000). In one study the genome-wide linkage scan analysis looking at the risk for nicotine dependence on the basis of the Fagerstrom Test demonstrated a significant association with a region on chromosome 5 in African Americans and on chromosome 7 for European American subjects (Gelernter et al. 2007). A different study assessing nicotine dependence with smoking quantity, HSI and the Fagerstrom Test showed a significant linkage to a region on chromosome 10q22 in African American subjects (Li et al. 2006). A number of other loci on chromosomes 6, 8, 16, and 19 were linked to various aspects of smoking behaviors (Swan et al. 2006). Smoking-induced dopamine release has also a genetic determinism. Smokers having genes associated with lower smoking-induced dopamine tone have been shown to have a greater smoking-induced dopamine release than those with alternate genotypes (Brody et al. 2006). Dopamine receptor and transporter genes have been associated to nicotine dependence (Batra et al. 2003). The catechol-O-methyltransferase (COMT) gene has an important role in dopaminergic circuits central to drug reward. Low COMT enzyme activity Met allele is associated with a decreased likelihood of becoming nicotine dependent (Beuten et al. 2006). There is evidence of a significant association between gamma amino butyric acid B2 (GABA2B) variants and nicotine dependence, implying that this gene might have role in the etiology of this drug addiction (Beuten et al. 2005). There is also genetic variability in the metabolism of nicotine that may help explain differences in both consumption and exposure. Metabolism of nicotine through the cytochrome P450 isozymes (CYP2A6 and CYP2D6) have displayed genetic polymorphisms and this will result in differences in nicotine metabolism. Both CYP2A6 and 2D6 genotype influences nicotine levels and smoking behavior. CYP2A6 slow metabolizers smoke fewer cigarettes per day compared to normal metabolizers and achieve higher levels of nicotine (Malaiyandi et al. 2006). Of note, the metabolism of the non-nicotine tobacco components is mostly through a different isoenzyme (will be discussed in more detail in the medication section of this chapter).

### Neurobiological Factors

Nicotine is readily absorbed in the lung from tobacco smoke or through the mucous membranes with smokeless tobacco. When smoking tobacco, nicotine enters the blood stream and is available to the brain within 7–9 s (even more quickly than with intravenous administration). Its peak effect occurs within 1 min, and effects are present after a single puff of smoke. With a half-life of approximately 2 hr, the level of nicotine in the blood stream gradually accumulates during the day, dropping but persisting overnight. Smokers, especially those with severe dependence, awaken in the morning in nicotine withdrawal and rapidly dose themselves. Nicotine receptors are ligand-gated ion channels with a variety of effects on the nervous, cardiovascular, immune and neuromuscular functioning (Changeux et al. 1998). The neuronal receptors are pentameric structures named on the basis of the α and β subunits. There are 11 identified neuronal nAChR subunits, including 8 α (α2-α9) and 3 β (β2-β4). Each subunit has 4 transmembrane spanning regions, M1–M4. The α4β2 is proposed to have 2 α4 and 3 β2 subunits.

As pointed out by Lloyd and Williams 2000 nicotine has a multiplicity of effects including “cognitive performance, vigilance, locomotor activity, body temperature, respiration, cardiovascular and gastrointestinal tract function, electroencephalogram activity, cortical blood flow and pain perception.” Most of these effects are also seen in humans. Nicotine is able to achieve the above by increasing the release of acetylcholine, dopamine, norepinephrine, serotonin, glutamate and gamma amino butyric acid (GABA) in the brain and the calciotonin and substance P in the spinal cord (Lloyd and Williams 2000). The beta2 nicotinic receptors are involved in the chronic, compulsive use of nicotine but not in the withdrawal syndrome (Besson et al. 2006). Some of nicotine’s effects are acute, while others appear only after chronic usage. It acts in two primary areas of the brain—the mesolimbic dopaminergic system (the brain reward pathway), which is related to the euphoriant effects of the drug, and the locus coeruleus, which mediates stress reactions and vigilance and relates to the higher mental and cognitive functions. There are specific nicotine receptor sites (the nicotinic cholinergic receptors) throughout the central nervous system in the hypothalamus, hippocampus, thalamus, midbrain, brain stem, and cerebral cortex. In addition, nicotine affects nearly all aspects of the endocrine–neuroendocrine system, including the catecholamine, serotonin, corticosteroid, and pituitary hormones. Its endocrine effects are mediated via the hypothalamic–pituitary axis and the adrenal medullary cortex. Centrally it causes release of acetylcholine, norepinephrine, serotonin, dopamine, vasopressin, growth hormone, corticotropin, cortisol, prolactin, and endorphins.

Nicotine has stimulant and depressive effects on both the central and the peripheral nervous systems. It also affects the cardiovascular system, the gastrointestinal system, and the skeletal motor system. Nicotine stimulates the cholinergic nervous system (sympathetic and parasympathetic).

Nicotine is a highly addictive substance that causes physical and psychological dependence that is similar to that of opiates and other substances of abuse (Office on Smoking and Health 1988, Henningfield 1984, Jarvik and Henningfield 1988). It is highly reinforcing, leading to compulsive use (Henningfield and Goldberg 1983). From a neurobiological perspective, there is strong evidence that the rewarding effects of smoking are mediated through the dopamine reward pathway, the mesolimbic dopamine (Balfour and Fagerstrom 1996). Nicotinic acetylcholine receptors, the site of action of nicotine, have been found on mesolimbic dopamine neurons (Clark and Pert 1985). Effects are related to dose, and tolerance to its actions develops rapidly, resulting in increased intake. Smokers adjust smoking behavior to regulate and maintain the level of nicotine in the blood stream. A withdrawal syndrome develops in response to reduced intake or total abstinence and involves both physiological and psychological symptoms (Benowitz
Withdrawal symptoms overlap with those of alcohol and other substances of abuse (Hughes et al. 1994). The literature on the biology of the nicotine withdrawal state points to reduced dopaminergic, adrenergic, and norepinephrine function (Fung et al. 1996, Ward et al. 1991). In addition to the physiologically addictive aspects of nicotine, smoking is highly conditioned to cues in the environment.

Psychological Factors: Psychological dependence involves the perceived benefits/reasons a person smokes, such as a perception that they are able to improve mood and sense of well-being, to satisfy craving, and to provide stimulation and relaxation (Goldstein et al. 1991). Through this variety of central and peripheral actions, nicotine improves mood and decreases anxiety; decreases distress in response to stressful stimuli and decreases aggression; improves overall cognitive function and performance (improves reaction time, concentration, vigilance, and stimulus-processing capacity, increases attention, memory and learning, improves the ability to disregard irrelevant stimuli); and decreases the appetite for simple carbohydrates, decreases stress-induced eating, and increases resting metabolic rate. Many individuals soon become tolerant to these effects so that they smoke not to achieve them, but rather to avoid withdrawal symptoms. The direct beneficial effects of nicotine on mood and concentration become highly positive reinforcements, as do associated social context and behaviors linked with smoking, which then can act as powerful triggers for relapse during attempts at cessation. Individuals’ expectations related to smoking are influential factors that counter the obvious health risks. For women these beliefs are also in the context of sociocultural attitudes that reinforce the belief that smoking helps to manage and control mood (anger, stress, depression), control weight gain, and increase an adolescent’s sense of being independent and trendy.

Social/Environmental Factors
The social component involves environmental and social cues that become associated with the behavior of smoking cigarettes, such as the association with drinking coffee or alcohol, talking on the telephone, taking a work break, or smoking at parties or social functions. In addition to genetic factors, smoking by family members normalizes this behavior, integrates tobacco use in daily activities, and also is a trigger for other’s use. For adolescents and college-age young adults, peer smoking and peer-group identification are also strong influencers of engaging in tobacco use, however, there are differences between ethnic groups. Family messages can moderate the effects of peer influence for some youth, and smoking can be perceived as “shaming” the family. Tobacco industry marketing and advertising strategies also try to promote psychological and social benefits of smoking in spite of the clear health risks. One strategy has been to engage celebrities and other public figures in being pro-smoking. The goal is to make smoking normal and to have youth see smoking everywhere (books, magazines, music, television, concerts, movies, sporting events, etc.).

Treatment
Algorithms and primers for nicotine-dependence treatment have been developed, including from the American Psychiatric Association (1996) and Work Group on Substance Use Disorders, et al. (2006) and the US Public Health Service (Fiore et al. 2000). For smokers not yet ready to quit, use of interventions to increase motivation and presentation of information about treatment options are appropriate. Discussing reasons for the person to consider quitting—for example, health consequences specific to the individual—and the factors that may have prevented an attempt is important. Written materials and brief advice from the physician are methods of providing such information and increasing motivation. Preparation for quitting may include self-monitoring or keeping a diary of smoking, planning rewards for successful abstinence, and making a list of reasons for and potential benefits of quitting. Sources of social support should also be identified.

Formal treatment options have expanded rapidly in the past 30 years to include seven FDA-approved medications, a range of effective psychosocial interventions including internet and phone-line services. Unfortunately, few individuals receive combined medications and therapy treatment only 5% of smokers who make a 24-hr quit attempt receive counseling as part of their treatment (Zhu et al. 2000).

Nicotine dependence, like other SUD, can be thought of as a chronic relapsing illness with a course of intermittent episodes alternating with periods of remission for most smokers. Hughes et al. (2004) examined the relapse curves of untreated smokers to determine when smokers relapsed after trying to quit without treatment. Most smokers relapsed within the first 8 days with abstinence rates ranging from 24 to 51% at one week, 10% to 20% at one month, and 3–5% at six months. With treatment, however, the overall abstinence rate is 20–25% by one year. However, these reported lower outcome rates do not consider the additive effects over time related to multiple quit attempts, since about 40–50% of smokers in the US have been able to quit smoking in their lifetime. Less than 25% of the individuals who have quit smoking are successful on their first attempt. Repeated failures are common before successful abstinence, with the average smoker attempting to quit five or six times before success. Recent prior attempts at quitting do increase the odds that individuals will be able to quit smoking on a future attempt. Relapse can occur even after a long time of abstinence, with about 33% of former smokers who are abstinent for 1 year eventually relapsing 5–10 years after cessation.

Treatment Goals
Nicotine dependence treatment targets severity of the problem, co-occurring disorders, and the different motivational levels to change. Treatment is provided in a range of levels of intensity of care (self-help, brief treatment, and once or twice per week outpatient treatment) and may include different modalities (self-help guides, internet resources, medications, and individual or group therapy). Treatment begins with an evaluation of the key biological, psychological, and social factors that are most significant for the individual in the initiation and maintenance of tobacco dependence. Several factors have been found to predict worse outcomes at smoking cessation (Kabat and Wynder 1987) (Table 62–2). Predictors include individual factors, manifestations of the addiction such as severity of withdrawal, and social and environmental circumstances. Treatment planning considers including biological and psychosocial treatment interventions.
Overall Approach to Treatment and Phases of Treatment

The general approach to the treatment of nicotine dependence considers three phases of treatment (engagement, quitting, and relapse prevention) (Table 62–3). Each phase of treatment includes consideration of three primary biopyschosocial factors: biological, psychological, and social factors effecting nicotine dependence outcomes. The importance of each of the biopsychosocial factors in initiating and maintaining smoking can vary considerably in different individuals. As a result, smoking cessation interventions should be tailored to the individual and his or her particular circumstances. This may be one reason why “one size fits all” generic treatment interventions have had such a low success rate. It must also be kept in mind that nicotine dependence is as complex in its components and determinants as other addictions and that more comprehensive multi-component treatment may be required.

When a smoker is ready for a cessation attempt, a “quit date” should be selected. After cessation, close monitoring should occur during the early period of abstinence. Before the quit date, the person should be encouraged to explore and organize social support for the self-attempt. Plans to minimize cues associated with smoking (e.g., avoiding circumstances likely to contribute to relapse) are important, as is considering alternative coping behaviors for situations with a higher potential for relapse. A telephone or face-to-face follow-up during the first few days after cessation is critical because this is the time that withdrawal symptoms are most severe, with 65% of patients relapsing by 1 week. A follow-up face-to-face meeting within 1–2 weeks allows a discussion of problems that have occurred (e.g., difficulties managing craving) and serves as an opportunity to provide reinforcement for ongoing abstinence. Even after the early period of abstinence, periodic telephone or face-to-face contacts can provide continued encouragement to maintain abstinence, allow problems with maintaining abstinence to be addressed, and provide feedback regarding the health benefits of abstinence. If a detoxification/quit attempt with pharmacotherapy alone fails, psychosocial treatments and the use of higher NRT dosages/multiple medications are possible clinical next steps. If pharmacotherapy is unacceptable or contraindicated, behavioral therapy (BT) alone should be provided. Failure with pharmacotherapy or BT alone suggests the need for more detailed in-depth assessment and more intensive and multimodal interventions.

### Table 62–2 Factors Predicting Worse Outcomes in Nicotine Dependence Treatment

| Physical reactivity (pulse, blood pressure, etc.) to smoking-related cues |
| Family and friends who are current smokers |
| Lack of social support from spouses, partners, family members, friends |
| Deficits in social skills and assertiveness |
| Higher severity of withdrawal symptoms |
| Limited ability to cope with effects occurring in response to cues or triggers |
| Depressed mood |

### Table 62–3 Three Phases of Nicotine Dependence Treatment

**Engagement Phase**
- Do a comprehensive evaluation of nicotine use and dependence
- Provide MET personalized feedback from the assessment
- Assess motivational level to quit and attempt to set a target quit date
- Explore previous quit attempts—what worked? What did not work? What triggered the return to tobacco use?
- Assess patient preference for treatment (medications, psychosocial treatments, group vs. individual, self-help, etc.) and provide education on treatment
- Create a treatment plan
- Strengthen and renew patient’s motivation to quit smoking (MET orientation)
- Identify cues and triggers for usage
- Self-monitoring of smoking behavior (write down when use)
- Help patients gain understanding of their own tobacco use patterns
- Help increase knowledge about triggers and cues
- Help patients understand environmental influences on their smoking
- Begin education about tobacco, nicotine dependence, withdrawal symptoms, etc.
- Begin disconnecting smoking behavior and linked behaviors (no smoking while driving car, talking on phone, during meal time, etc.)
- Help them get medication evaluation and medications for the quitting phase

**Quitting Phase**
- Start medications on quit date (NRT) or before quit date (bupropion), sometimes begin NRT (gum, spray, inhaler, not patch) in small amounts and reduce tobacco usage in an equivalent or greater amount
- Teach specific coping techniques for handling withdrawal symptoms, cues/triggers, and how to enhance social support
- Help patient prepare emotionally, behaviorally, and physically for the quit date and the early abstinence period
- Help identify support systems, anticipate challenges, and address ways to handle people, places, things, and mood challenges
- Address nutrition and exercise components
- Address role of family/friends in supporting or sabotaging treatment
- Continue to strengthen client’s resolve to quit
- Continue relapse prevention therapy approaches
- Assess triggers to craving and use and high-risk situations
- Coping with cravings, thoughts, and urges
- Problem solving
- Smoke refusal skills
- Planning for emergencies
- Seemingly irrelevant decisions
- Relapse analysis for slips

**Relapse Prevention Phase**
- Continue relapse prevention strategies for long-term abstinence
- Reinforce specific coping skills, including mood management and patient specific triggers
- Teach positive coping skills for dealing with frustration and anxiety
- Compliment success and provide encouragement
- Continue focus on maintaining motivation and commitment for abstinence
- Monitor progress
- Provide treatment within your discipline and make referrals when appropriate
- Encourage the use of peer support such as Nicotine Anonymous help the client gain personal insight and keep growing in their recovery
- Manage any relapses.slips to continue the course
- Continue medications as needed
of nicotine replacement appears to be minimal. The intent is to substitute a safer, medically prescribed substance for nicotine and then to taper the substance in a manner that prevents or minimizes withdrawal. This agonist approach is similar to the use of benzodiazepines to treat acute alcohol withdrawal or methadone substitution and taper in the treatment of heroin addiction. The substituted nicotine initially prevents significant withdrawal symptoms that may lead to relapse during the early period of smoking cessation. The substituted nicotine is then gradually tapered and discontinued. Replacement produces a lower overall plasma level of nicotine than that experienced with smoking. Replacement not only avoids the strongly reinforcing peaks in plasma level but also prevents the emergence of withdrawal symptoms by maintaining the nicotine plasma level above a threshold. Typically, each cigarette contains about 13 mg of nicotine and about 2 mg is absorbed into the body.

Nicotine gum, approved in 1984, was the first NRT approved and it slowly releases nicotine from an ion exchange resin when chewed. The nicotine released is absorbed through the buccal mucous membranes. The NRT gum is available in doses of 2 and 4 mg, and the recommended dosing is in the range of 9–16 pieces/day. Peak blood nicotine levels achieved are low (approximately 10–15 ng/mL) compared with those in dependent smokers (15–100 ng/mL). Placebo-controlled studies of nicotine gum treatment in smoking cessation clinics show a doubling of abstinence rates (Lam et al. 1987) with the 4-mg dose possibly providing a better outcome than the 2-mg dose for persons who are highly nicotine dependent (Tonnesen et al. 1988). Nicotine gum is more effective when used in conjunction with some type of psychosocial intervention, particularly BT (Lam et al. 1987). Outcome is more positive when a definite schedule for gum use is prescribed—for example, one piece of gum per hour while awake—than when used on an as-needed basis (Fagerstrom and Melen 1985, Goldstein et al. 1989). Some studies suggest that it is also more effective when used for longer than 3 months (Fagerstrom and Melen 1985). Tapering may be necessary after 4–6 months of use, especially for individuals using higher total daily doses of gum. Nicotine gum is often not effectively utilized in patients with temporomandibular joint problems, dental problems, and dentures. Nicotine gum requires a highly motivated patient and a good deal of time in instructing the patient in proper use of the gum. Many individuals find the gum difficult to learn to use properly. Patients must be instructed that nicotine gum is not like bubble gum and that the gum is crunched a few times and “parked” between the gum and cheek. It should not be used soon after drinking acidic substances such as coffee,

### Treatment Benefits

Treatment of nicotine dependence with resultant abstinence can result in highly beneficial health effects (US Department of Health and Human Services 1990). In addition to nicotine being in tobacco, unprocessed tobacco smoke includes more than 2,500 compounds, and when manufactured additives and other compounds are taken into account, about 4,000 compounds are present (U.S. Department of Health and Human Services 1988). Research has demonstrated that the vast majority of harm associated with cigarettes is attributable to the byproducts of smoking rather than to the effects of nicotine (Slade 1999). Educating individuals and families about these benefits of abstinence from smoking can be helpful. Short-term effects (within 1 month) include a significant reduction in respiratory symptoms and respiratory infections such as influenza, pneumonia, and bronchitis. Excess risk of death from coronary heart disease is reduced after 1 year and continues to decline over time. In patients with coronary heart disease, smoking cessation decreases the risk of recurrent myocardial infarction and cardiovascular death by 50%. By 10–15 years of abstinence the mortality rate from all causes returns to that of a person who has never smoked. Pulmonary function can also return to normal if chronic obstructive changes have not already occurred at the time of cessation, and even with obstructive changes pulmonary function can improve with abstinence.

### Psychiatric Medication Management Issues with Abstinence

Tobacco (not nicotine) is metabolized by the P450/1a2 isoenzyme and enhances the metabolism of psychiatric medications that are also similarly metabolized by this isoenzyme (Lee and D’Alonzo 1993, Goldstein et al. 1991, Work Group on Substance Use Disorders, et al. 2006). Quitting smoking will eliminate tobacco’s effects on the P450/1a2 isoenzyme, which will typically cause an increase in the blood levels of those medications also metabolized by that isoenzyme (including several psychiatric medications metabolized through 1A2), potentially resulting in increased side effects or other adverse events, including increased noncompliance due to the side effects (Lee and D’Alonzo 1993).

### Somatic Treatments

#### Pharmacological Intervention

Pharmacological interventions have become an important component of treating nicotine dependence. Approaches used parallel other addictions in treating acute withdrawal (detoxification), protracted withdrawal, and even maintenance for harm reduction. The primary medications are NRT, bupropion, and varenicline. All seven of these modalities are FDA approved and have demonstrated efficacy (Table 62–4).

Nicotine replacement therapy (NRT) is the most widely used medication option and is available over-the-counter (patch, gum, and lozenge) or by prescription (patch, gum, spray, and inhaler). The principle behind nicotine replacement is that nicotine is the dependence producing constituent of cigarette smoking, and that smoking cessation and abstinence can be achieved by replacing nicotine without the harmful impurities in cigarette smoke. The abuse liability

Chapter 62 • Substance Abuse: Nicotine Dependence 1157
soda, or orange juice because the acidic environment in the mouth interferes with its release and absorption. Specifications of the proper use of nicotine gum are provided by Schneider 1988. Side effects and adverse effects include local irritation in the mouth, tongue, and throat, mouth ulcers, hiccups, jaw ache, gastrointestinal symptoms (flatulence, indigestion, nausea), anorexia, and palpitations. About 6–9% continue to use nicotine gum for 1 year—this may reflect some risk for dependence. However, most individuals report that they still prefer the tobacco product and are using the nicotine gum only to avoid the tobacco usage (Hajek et al. 1988). The nicotine lozenge was FDA approved in 2002 and is similar in dosing to the nicotine gum and less complicated to use.

The nicotine patch transdermal delivery system provides continual sustained release of nicotine, which is absorbed through the skin. This form of nicotine replacement more than doubles the 1-year cessation rate (Hughes 1994b). There is a dose–response relationship, with patients receiving higher doses attaining higher cessation rates. The nicotine patch eliminates the conditioning of repeated nicotine use, which remains present with the use of other NRT products. Compliance rates are higher because it involves once-daily dosing and its administration is simple and discreet. The typical starting dose of NRT patch is 21 or 15 mg patch, however, in some cases multiple patches are used. Lower dose patches available at 7 and 14 mg are used to taper after smoking cessation. The patch delivers approximately 0.9 mg of nicotine/hr. Steady-state nicotine levels are 13–25 ng/mL and the highest levels are seen soon after patch application. The nicotine patch is often used for a total of 6–12 weeks but can be used for much longer (American Psychiatric Association 1996). The transdermal patch does not allow for self-titrated dosing, craving, and nicotine withdrawal symptoms like the other NRT routes (gum, spray, inhaler, lozenge), however, the nicotine blood levels are significantly less than with smoking. The patch can be used more discreetly and can be used despite dental or temporary mandibular joint problems. Specifications on the proper use of transdermal nicotine are provided by Gourley (1994). Although the nicotine patch is well tolerated, about 25% of patients have significant local skin irritation or erythema and 10% discontinue the patch because of intolerable side effects. Other side effects include sleep problems with the 24-hr patches. In a few cases, nicotine toxicity developed when smokers continued their usual heavy cigarette smoking while using the transdermal nicotine patch. However, transdermal nicotine may cause less activation of blood coagulation and have less impact on the sympathetic nervous system than nicotine polacrilex gum; therefore, it may be preferable in the presence of cardiac disease (Rennard et al. 1991, Benowitz et al. 1993). One study found that it could be safely used in patients with stable coronary artery disease (Anonymous 1994, Gross et al. 1989, Hughes 1995).

Some experts suggest using nicotine gum concurrently with transdermal nicotine on an as-needed basis to cover emergent withdrawal symptoms or craving not controlled by replacement from the transdermal patch, whereas others suggest simply increasing the dose of the transdermal patch or using gum initially and then switching to the patch (Gourley 1994, Fagerstrom et al. 1993). The nicotine nasal spray is rapidly absorbed and produces a higher nicotine blood level than does transdermal nicotine or gum. A single dose of the spray delivers 0.5 mg to each nostril and it can be used one to three times/hr. It has been suggested that the effective daily dose in nicotine dependent smokers is 15–20 sprays (8–10 mg/day) (Balfour and Fagerstrom 1996). Onset of action of the spray is the most rapid of all nicotine replacements; nicotine levels in plasma reach 10–20 ng/mL (Balfour and Fagerstrom 1996). An initial concern about the nasal spray had been the potential for abuse because it has the most rapid absorption rate of the NRTs. It replicates repeated administration of nicotine in smoking, resulting in reinforcing peaks in the plasma level of the drug. Side effects of the spray include local airway irritation (i.e., coughing, rhinorrhea, lacrimation, nasal irritation), but tolerance to these local effects appears to develop. Systemic effects include nausea, headache, dizziness, tachycardia, and sweating (Balfour and Fagerstrom 1996, Sutherland et al. 1992).

The nicotine inhaler provides nicotine through a cartridge that must be “puffed.” It mimics the upper airway stimulation experienced with smoking, however, absorption is primarily through the oropharyngeal mucosa. Although the blood level of nicotine is lower than with other forms of nicotine replacement (8–10 ng/mL), the inhaler has been shown to be effective (Tonnesson et al. 1993). Controlled trials (Schneider 1996) indicate 1-year abstinence rates of 17% for the nicotine inhaler and 8% for placebo. Side effects of the inhaler and spray include local irritation, cough, headache, nausea, dyspepsia, the need for multiple dosing, and the impossibility of discreet use.

**Bupropion**, the non-nicotine pill FDA-approved medication option, is a heterocyclic, atypical antidepressant that blocks the reuptake of both dopamine and norepinephrine. Its efficacy as an aid to smoking cessation was first demonstrated in three double-blind placebo-controlled trials in nondepressed chronic cigarette smokers (Hurt 1997) (28% versus 4% abstinence at 12 weeks) (Ferry et al. 1992). It was well tolerated and did not produce weight gain. The effects in smoking cessation appear to be unrelated to its antidepressant properties (Hurt 1997). Smoking cessation rates appear to improve further when bupropion is combined with the nicotine patch (Nides 1997). In all studies, adverse events had a low incidence and included dry mouth, insomnia, nausea, and skin rash. There have been no reports of seizures in any smoking cessation study to date, however, this agent should not be used in patients with a history of seizure disorders.

**Varenicline (Chantix):** In May 2006 the Food and Drug Administration approved Chantix (varenicline tartrate) for smoking cessation. Varenicline is an α4β2 nicotinic acetylcholine receptor partial agonist. The α4β2 receptor is thought to mediate the rewarding properties of nicotine through the release of dopamine in the mesolimbic system, and in particular nucleus accumbens. The agonist effect on dopamine release is 35–60% that of nicotine, considered sufficient to reduce craving and withdrawal. Varenicline has also a competitive antagonist effects on nicotine due to the higher affinity for the α4β2 receptor, which is thought to blunt the reinforcing effects of smoking (Keating and Sidiqui 2006). Varenicline’s maximum plasma concentration is reached after 3–4 hr and following repeated oral doses the steady-state occurs within 4 days. The medication has a 20% plasma protein binding and a half-life of 24 hr. It is eliminated 92% unchanged in the urine. No meaningful clinical pharmacokinetic drug-drug interactions have been
identified. There were no pharmacokinetic differences due to age, race, gender, smoking status or use of other medications (Keating and Siddiqui 2006). The efficacy of Varenicline in smoking cessation was demonstrated in six clinical studies Gonzales et al. 2006, including several studies finding better outcomes with Varenicline compared to Bupropion (Jorenby et al. 2006, Nides et al. 2006). Varenicline should be started 1 week before the set date for patients to stop smoking. The approved course of treatment is 12 weeks. The recommended dose of 1 mg twice daily should be arrived at after a 1-week titration. For the first 3 days the patients should take 0.5 mg, followed by 0.5 mg twice a day for the next 4 days and then 1 mg twice a day for the rest of the therapeutic period. The adverse reactions leading to discontinuation include nausea, headache, insomnia and abnormal dreams. The most common adverse events occurring in more than 5% or twice the rate seen with placebo were nausea, sleep disturbance, constipation, flatulence and vomiting (Keating and Siddiqui 2006).

Non-FDA Approved Medications
Several medications have been studied with some noted efficacy although not FDA approved. Clonidine has been evaluated in both oral (0.1 mg) and transdermal forms (0.1–1.3 mg) (Hughes 1994a). Clonidine, an antihypertensive drug with central noradrenaline/sympatholytic activity, is a presynaptic alpha-2-receptor agonist that has been used extensively in the management of opiate and alcohol withdrawal. It appears to be more effective in women than in men and may be less effective in patients with a history of MDD (Glassman et al. 1985, Covey and Glassman 1991). Potential side effects and adverse effects include sedation, dry mouth, and hypotension. Buspirone, a non-sedative, nonaddictive, nonbenzodiazepine anxiolytic agent, has been shown in some pilot studies to decrease craving, anxiety, and fatigue during withdrawal from nicotine, however, effects on cessation rate have been mixed and limited (Hughes 1994a). A few studies suggest that some of the traditional tricyclic antidepressants may help reduce nicotine withdrawal, craving, and relapse, including doxepin (Edwards et al. 1989), imipramine (Jacobs et al. 1971), and nortriptyline (Humfleet et al. 1996, Hall et al. 1998). However, the side effects of these tricyclic antidepressants can include increased appetite, weight gain, dry mouth, blurred vision, constipation, urinary hesitancy, and sedation.

Other medication strategies that have been evaluated include tiagabine, Rimonabant, Selegiline, and immunological approaches. The activation of nicotinic receptors is moderating the release of acetylcholine, dopamine, serotonin, noradrenaline, GABA and glutamate (Watkins et al. 2000). GABA inhibits and glutamate stimulates dopamine release (Mansvelder et al. 2002). Preclinical research suggests that medications enhancing GABA decreases the rewarding effects of stimulants like nicotine. Soutougli et al. (2004) showed that 8 mg of Tiagabine diminished the craving for cigarettes and increased the cognitive performance in the Classical Stroop test compared to placebo. Rimonabant is a selective cannabinoid CB1 receptor developed for the treatment of obesity, tobacco smoking and cardiometabolic risk factors. Three Studies with Rimonabant and Tobacco Use (the STRATUS trials) were done recruiting 6,500 patients in the USA and Europe looking at rimonabant in doses of 5 mg and 20 mg daily against placebo on smoking cessation at 10 and 50 weeks. In the STRATUS-US the quit rate was 26.7% in the 20 mg group as compared to 16.1% for placebo. STRATUS-Europe did not show significant differences. STRATUS-Worldwide demonstrated lower relapse rate after 1 year in the 20 mg group (41.5% vs. 32.5%) (Wierzbicki 2006, Siu and Tyndale 2007). Monoamine oxidase-B (MAO-B) is involved in the degradation of dopamine, tyramine and phenylethylamine. There is evidence from PET studies that MAO-B is reduced in the brain of smokers. After smoking cessation the enzyme activity returns to normal leading to a drop in the level of dopamine and resulting craving. Selegiline, a MAO-B inhibitor increasing the availability of dopamine, was shown to reduce craving and to mitigate the need for NRT (Biberman et al. 2003). It also improved the 52-week abstinence rate even though the result did not achieve statistical significance. The immunologic approach to treating nicotine dependence involves passive or active immunization against nicotine. The antibodies decrease the amount of unbound nicotine in the serum which is the fraction able to enter the brain and reach the receptors. As a consequence the rewarding and reinforcing effects of smoking are diminished. Also the bound fraction of nicotine is protected against rapid metabolism and excretion. The net results are prolonged nicotine effects and a reduced rate of nicotine intake in order to obtain the desired effects (LeSage et al. 2006). One of the several companies involved in the development of vaccines, Cytos Biotechnology, posted last year on the website http://www.cytos.com (accessed on January 10, 2007) the results of Phase II study regarding the efficacy of their product, CYT002-NicQb. The data showed that CYT002-NicQb promoted and sustained continuous abstinence from smoking from the week 8 to 52 after start of treatment in participants who achieved high antibody levels upon vaccination versus those participants who received only counseling and a placebo (p = 0.012).

Combination Treatments
Combined NRTs/bupropion or serial pharmacotherapeutic approaches may also be beneficial, especially in more difficult to treat cases of nicotine dependence. For example, combining the patch with other nicotine replacement medications like nicotine gum or the spray allows for both more rapid onset of action and reduction of withdrawal symptoms through steady levels of nicotine released by the patch. Combining nicotine replacement with nonnicotine replacement strategies (e.g., bupropion and nicotine patch) has been beneficial in further improving outcomes in some studies and is common in clinical practice. The combination approach offers the advantage of multiple neurobiological mechanisms of actions. In addition, many researchers increasingly believe that periods of pharmacotherapy should be extended, although the issue of whether longer-term pharmacotherapy is beneficial in improving cessation rates remains unresolved. There may be some smokers who are unable to stop smoking without ongoing nicotine replacement, similar to individuals dependent on heroin who must be maintained on methadone. Although long-term/maintenance use of NRT requires further study, successful maintenance in smokers who have chronic relapses would potentially reduce a number of the serious health risks associated with smoking, in spite of individuals still being exposed to the effects of nicotine. Ongoing maintenance
antidepressant treatment may also be necessary for a time for some individuals with a history of serious depressive illness or for those who have had significant depressive symptoms emerge on cessation that do not improve with time.

**Psychosocial Treatments**

In contrast with the treatment of other SUD, psychosocial treatment is underutilized and has not evolved to be the cornerstone of treatment. This limited utilization of psychosocial treatments does not match the very positive outcomes from either psychosocial treatments alone (25% 1-year abstinence with BT) or when combined with NRT or bupropion (50% improvement compared to NRT or bupropion alone), however, it does match the lack of health care coverage for this service. The underutilization of psychosocial treatment has become the cultural norm in nicotine dependence treatment. This may be due to several important considerations. These include: (1) Primary care practitioners most frequently attempt to address nicotine dependence and do not traditionally integrate BTs. (2) Nicotine dependence treatment is often not paid for by health care insurance companies. (3) Few behavioral health specialists have been formally trained in nicotine dependence treatments. (4) Mental health and addiction treatment programs have ignored addressing tobacco in those treatment settings, although this appears to be changing, and (5) Patients are unaware of this treatment modality and its success rates, and believe that medications or quitting cold turkey is all that is needed.

A great variety of psychosocial interventions have been developed to help in the treatment of nicotine dependence (Table 62–5). In general, the core psychotherapies in substance abuse treatment are motivational enhancement therapy (MET), cognitive–behavioral therapy (CBT), and 12-Step Facilitation. Psychosocial interventions, particularly Behavioral Therapy, have been shown to increase abstinence rates significantly (Ferry et al. 1992). However, only 7% of smokers attempting to quit smoking are willing to participate in BT (Ferry et al. 1992). In addition, it is more expensive than pharmacotherapy and more labor-intensive.

**Brief or Minimal Medical Professional-Delivered Interventions/Advice**

Even a brief face-to-face intervention by a physician or other medical staff can increase the likelihood of cessation 2–10-fold (Klesges et al. 1990). The impact of physician’s brief advice to quit has received the most study relative to other disciplines such as nursing, however, clearly all disciplines have opportunity to make an impact. Physicians can inquire about a patient’s smoking status, urge the patient to stop smoking, and spend a brief time counseling the patient about cessation strategies. Multiple follow-up interventions, even telephone contacts by other medical staff, can further improve the cessation rate. Resources are available to assist physicians in providing effective antismoking interventions, which can even be used by those not highly skilled in counseling. Physicians’ advice appears to be most successful with patients with a serious medical problem or specific medical reason for quitting (e.g., pregnancy or congestive heart disease). In addition, because an estimated 70% of smokers in the US visit their physicians at least once a year, an important opportunity exists for providing this type of smoking cessation intervention.

MET is especially helpful for the smoker who continues to be ambivalent about quitting. MET strategies aim to enhance the smoker’s commitment and motivation to quit smoking. The therapist maintains a patient-centered approach and is empathic and optimistic. The therapist adopts a focused but non-confrontational style while examining the effect of tobacco use on the smoker’s life and collaborating with the smoker to develop and implement a treatment plan. MET is compatible with Prochaska and DiClemente’s stages of change model, in which patients are assessed as being in the precontemplation, contemplation, preparation, action, or maintenance stage of change. This model also emphasizes the importance of tailoring interventions to the patient’s motivational level (Prochaska et al. 1992). Interventions aimed at immediate cessation of tobacco are often ineffective for patients in the contemplation or pre-contemplation stage especially since there is usually not a powerful external motivator to maintain compliance. Without an external motivator, a confrontational approach is likely to provoke resistance and treatment drop-out. Realistic goals for the poorly motivated patient are to simply increase awareness of the impact of tobacco and the possibility of change. Later interventions may involve creating a change plan and discussing feelings of ambivalence, including the patients’ perceived benefits of using tobacco and reasons to stop using tobacco (Miller et al. 1995). An important initial component of MET is to provide personalized feedback on how tobacco may be affecting their lives and others. Feedback that has impact might include the cost of tobacco products during a year, negative health consequences, likelihood for health improvement in case of abstinence, social stigma toward smoking, CO levels, interaction of tobacco metabolism and specific medications, and other health consequences (wrinkles, impotence, etc.).

**Behavioral and CBT approaches** have been developed to be effective treatments for nicotine dependence, and as for any other addiction CBTs are one of the core therapy approaches. BTs often include a self-monitoring assessment phase that is linked with specific treatment interventions. The self-monitoring involves the identification of affective, cognitive, and environmental cues that trigger smoking behavior. Understanding the cues and triggers for usage are helpful in guiding the CBT approach of relapse prevention. Relapse prevention training helps clients develop problem-solving skills for coping with situations or emotions that might be likely to precipitate relapse, as well as alternative behaviors appropriate for high-risk situations. Individuals learn to manage an abstinence violation (“slip” or “lapse”) in a way that prevents a relapse to smoking. Discussing ways
of managing withdrawal symptoms, such as sleep disturbance and irritability, can also be useful and, if performed in a group setting, can allow individuals to learn from others struggling with cessation. Stress management and relaxation training are often also used as adjunctive interventions, individually or in a group setting. Problems with the group format include a generally low compliance rate, lack of availability of groups in all geographical areas or at a given point in time, and patients’ reluctance to participate. Problems with the individual format include higher cost and the need for a larger number of counselors per population (Hajek et al. 1985).

In relapse prevention coping skills training, patients are taught skills to manage situations without resorting to smoking. Cognitive approaches involve specific techniques such as reframing or restricting thoughts related to smoking or replacing thoughts about smoking with thoughts intended to enhance motivation or self-efficacy. Assertiveness training can contribute to improved coping by helping patients to ask for assistance from significant others and to request that others refrain from smoking in their presence. One controlled trial found that a cognitive intervention focused on enhancing the regulation of affect produced a better outcome in smokers with a history of MDD, suggesting some potential benefit of providing more expensive, time-intensive interventions to specific populations of patients (Hall et al. 1992). Stimulus control strategies involve removing or altering cues that have been strongly associated with smoking, for example, avoiding certain situations that are likely to increase craving or trigger smoking. Cue extinction involves repeated exposure of the individual to cues or triggers associated with smoking. Through repeated episodes of exposure that are not followed by smoking, these cues and triggers gradually lose their power to provoke craving. Nicotine fading contrasts with an abrupt discontinuation of tobacco. In some cases, this includes switching to a different brand of cigarettes with lower nicotine, and it usually also focuses on gradually reducing the number of cigarettes smoked on a schedule over time, usually several weeks. Nicotine fading sometimes helps to make the transition from several packs of cigarettes per day to the reduced amount of nicotine during NRT and other treatments. Nicotine fading may help any smoker try to quit, however, the research results are mixed and more research must be done in this area. Another nicotine fading strategy focuses on disconnecting specific triggers and tobacco usage, for example, helping patients not to smoke while in the car, on the phone, or during mealtime. Sometimes this reduces the overall nicotine consumption in the day, and it has the effect of increasing the individual’s self-efficacy that they can begin to shape their behaviors and develop coping strategies to handle specific situations (American Psychiatric Association 1996). Aversive techniques include the use of rapid smoking and smoke holding. Rapid smoking involves inhaling cigarette smoke every 6 seconds until the smoker becomes ill. Several repetitions over several sessions are usually planned. Smoke holding involves holding smoke in the mouth and continuing to breathe. Both techniques have been found effective and safe even in patients with medical complications from smoking. A limiting factor in the use of these techniques is acceptability by the patient. In contingency contracting the patient participates in developing rewards for not smoking or punishment for smoking. As an example, a patient might give money to a friend or person overseeing the treatment. The money would be returned only if the patient successfully stopped smoking for a specified period.

Despite the fact that there has been little controlled research examining whether psychosocial intervention with spouses and significant others or families can increase abstinence rates, overall social support for individuals who are attempting to stop smoking appears to improve the outcome. Others in the smoker’s immediate family or social circle can be involved in their treatment through education about appropriate supportive behaviors. Concerned others can also be engaged in treatment to provide assessment information or to help enhance patient motivation.

Hypnosis, acupuncture, and laser therapy are three approaches that some individuals believe have helped them in their efforts to quit smoking, however, the empirical evidence does not support their use as reported by the most recent Hajek et al. (2005). Hypnosis claims to reduce (or even ameliorate) the desire to smoke and/or to fortify resolve to quit. The results of nine randomized trials of hypnotherapy compared to 14 different control interventions did not show a greater effect for hypnosis as compared to control interventions or to no treatment (Abbott et al. 1998). Acupuncture is a traditional Chinese therapy aiming to reduce withdrawal symptoms associated with quitting smoking by inserting needles in specific areas of the body. Laser therapy purported to work the same mechanisms of action as acupuncture—only using low-level lasers rather than needles. A very recent Cochrane review (White et al. 2006) concluded that these therapies are unlikely to help smokers to quit although the authors note that it is difficult to make firm conclusions because of poor methodology used in the studies of these approaches.

**Self-Help**

Many smokers have successfully quit smoking without participating in formal treatment (Fiore et al. 1990). Although only about 3–4% are successful during the past year, this success rate improves with multiple attempts and probable self-learning through trial and error and learning from others. Eventually about 50% of smokers are able to quit and more than 90% of successful quitters have been able to do so without the assistance of professionals or formal programs. These numbers reflect multiple factors including the limitations on access to treatment (nonexistent health insurance coverage and limited number of providers with expertise to help), the cumulative process of multiple attempts and learning from others and from self-help materials, and the severity of the nicotine dependence. The advantage of quitting without professional intervention is the decreased expense and time commitment, however, professional treatment may be necessary for higher severity cases that are often complicated by other behavioral health problems. The primary unassisted method of detoxification from nicotine dependence is precipitous cessation (cold turkey), which is used by more than 80% of smokers. This is followed by spontaneous strategies to handle cravings and triggers. Some smokers attempt to limit intake, taper the number of cigarettes smoked, or switch to a reduced tar or nicotine brand. Special filters and holders are also available to decrease the amount of smoke that is available from a cigarette. These methods are usually less successful because smokers have been shown to alter...
smoking behavior by increasing the frequency, volume, or duration of the inhalation to ensure maintenance of blood levels of nicotine adequate to prevent withdrawal symptoms (Moss and Prue 1982, Russell 1987). Some smokers use nonprescription pills that are analogues of nicotine, such as lobeline, to help manage or prevent withdrawal symptoms. These agents have not been shown to be effective in controlled studies (Hughes 1994a).

**Nicotine Anonymous**

Some geographical areas have Nicotine Anonymous groups that are structured similarly to Alcoholics Anonymous or Narcotics Anonymous groups. These groups are based on the 12-Step approach to recovery from addictions. Nicotine Anonymous is a relatively new organization (founded in 1985) and does not have the extensive network that other 12-Step programs like Alcoholics Anonymous or Narcotics Anonymous have developed. No formal controlled studies of the benefits of this intervention have been carried out. In addition, self-help written materials can play an important role in educating patients about the negative health effects of nicotine, the benefits of quitting, and the nature of the addiction. Self-help literature, internet resources, and Nicotine Anonymous can be effectively integrated into formal treatments of brief interventions, individual and group treatments. Even smokers with major health conditions, such as chronic obstructive pulmonary disease or cardiovascular disease, often have a difficult time maintaining abstinence. Numerous psychological and pharmacological treatments have been developed to assist with smoking cessation.

**Combined Psychosocial and Psychopharmacological Therapies**

All nicotine dependence treatment practice guidelines recommend the integration of nicotine dependence treatment medications (NRT and bupropion or varenicline) with behavioral and supportive psychosocial treatment approaches. Empirical evidence supports the finding that medications double the quit rate compared to placebo, and face-to-face BT can double the quit rate compared to minimal psychosocial intervention. BT also can increase medication compliance. Integrated treatment further increases the quit rate by another 50% and triples the outcome rate compared to a control group (Fiore et al. 1990). Nicotine dependence treatment guidelines by the American Psychiatric Association (1996, 2006), Agency for Health Care Policy and Research (1996), and the US Public Health Service (Fiore et al. 2000) all support integrated treatment, and are excellent sources of clinical and research information. Recent reviews and meta-analyses by Hughes (1995), Fiore et al. (1990), Baille et al. (1994), and Ziedonis et al. (2001) also support integrated treatment.

Compared to treating other addictions, there is philosophical support among clinicians for integrated treatment for nicotine dependence. This support is probably due to the fact that there are effective medications for nicotine dependence and the absence of controversies that have plagued other fields of addiction, particularly with regard to abstinence versus controlled use and medical versus behavioral approaches. Unfortunately, few smokers use BT because of the added cost, lack of local expertise, waiting time for treatment, and preference against group therapy. Efforts are being made to make BT more acceptable to smokers and to triage smokers to more intensive therapies as needed.

Hughes (1995) performed a meta-analysis of existing studies of combined psychosocial and pharmacological treatments for smoking cessation and found that the addition of nicotine gum to psychosocial treatments resulted in a 60−80% increase in abstinence, whereas addition of transdermal nicotine produced a 40−80% increase in abstinence. Addition of psychosocial therapies to nicotine replacement (gum or transdermal) resulted in a 60−80% increase in abstinence with nicotine gum and an odds ratio of 3.1 for transdermal nicotine. Studies of combined nicotine gum and psychosocial treatment showed additive, possibly synergistic positive effects.

**Problems in Management**

Repetitive Relapse: Although generally effective treatments have been developed for nicotine dependence, research is limited on treatment matching and determining the timing and duration of interventions. Questions regarding treatment specificity become even more complicated when treating smokers who have experienced repeated relapses, those who have been unable to stop smoking, or those who are able to maintain abstinence for only brief periods (Table 62–6). Treatment algorithms applied to the general population of smokers may have little relevance to the smoker who suffers chronic relapses. At this time, the literature on any specific interventions designed to prevent relapse to smoking, is inconclusive (Hajek et al. 2005). The authors (Hajek et al. 2005) describe the current relapse prevention studies as insufficient for detecting small differences between interventions—whether due to low statistical power or less than ideal experimental designs. Given the lack of data regarding treatment specificity, the key to planning interventions with smokers who have had repeated relapses is a comprehensive reevaluation to determine the unique set of factors related to repeated relapse in a given individual. This analysis can serve as the basis for developing an individualized comprehensive treatment program. In approaching evaluation and treatment planning, it is important not to view the smoker as a “failure” but rather to understand how neglecting to adequately understand the illness of nicotine dependence as it presents in the particular patient has resulted in ineffective treatment with a poor outcome. It is also important to realize that even our “intensive” nicotine dependence treatments pale compared to the intensity of addiction treatment for other substances (residential treatment, intensive outpatient programs, partial hospitalizations, etc.). In some cases, the repeat relapsing smoker would appear to benefit from more intensive interventions, multiple-component interventions, or both. However, in some cases these smokers did not receive

---
an adequate single intervention and did not ever receive an adequate “dose” of treatment. In the latter case, treating with a previously used single therapy and ensuring the adequacy of all aspects of the treatment may be appropriate. For example, a patient may have relapsed despite being treated with NRT gum because an intermittent dosing schedule was prescribed or because of improper use of the gum, both of which resulted in an inadequate overall dose of nicotine replacement followed by withdrawal symptoms and relapse. Such a patient might be treated with NRT transdermal patch to improve compliance and ensure a stable plasma level of nicotine to prevent withdrawal symptoms. Alternatively, the dose of nicotine the patient was prescribed may have been too low and the withdrawal symptoms too substantial to refrain from relapsing. In some rarer cases, the dose may have been too high, leading to adverse effects, discontinuation of the transdermal patch, and subsequent relapse. Providing a lower dose that is tolerated may lead to successful cessation with a single previously used treatment. An inappropriate single treatment may also have been provided, as in the case of a male patient treated with one of the non-FDA-approved medications of clonidine for the management of nicotine withdrawal symptoms when research data show that clonidine is effective primarily in women. A single treatment may have been inappropriate in that it was focused on an area that is not critical, whereas an area critical to the maintenance of abstinence has been overlooked. A patient without a high degree of physiological dependence on nicotine may have been treated with nicotine replacement while the fact that her husband is a heavy smoker was not addressed. A future cessation attempt might be preceded by conjoint sessions with the spouse to motivate him also to stop smoking, to educate him about the psychological effects of smoking and the behavioral changes that may accompany cessation, and to enlist his aid in providing a more supportive environment for nicotine dependence treatment (e.g., not smoking at home or in the presence of the patient).

Even with multiple interventions, an important aspect of relapse may have been overlooked. For example, both nicotine replacement and group therapy may have been provided to a woman who then made a conscious decision to start smoking again to lose the weight gained during the cessation attempt. In this case, educating the woman about the effects of nicotine on metabolism, helping her develop a healthy diet and exercise plan, and providing her with a cognitive intervention to assist her in reframing and accepting the weight gain as a return to a normal weight that was abnormally lowered by nicotine might make a critical difference in the success of the cessation attempt. Planning to address weight loss at a future time after abstinence has been solidly established is an example of how serial treatment interventions might be used successfully. Alternative modalities might also be appropriate. For example, a group BT might have been prescribed for a person who was so anxious and uncomfortable in the presence of others that he or she avoided attending many of the sessions and was unable to participate even when present. Providing individual sessions in which key elements of the BT are presented and discussed might lead to more successful cessation. A history of depressive episodes or current depressive symptoms may have been overlooked. In such a case, or when significant depressive symptoms have emerged during the acute withdrawal period, pretreatment with antidepressant medication added to the prior treatment regimen may result in successful cessation.

The family and home environment should also be reassessed to determine if the smoker is receiving adequate support from the spouse, significant other, family, and general social circle. Conjoint marital or family sessions may be beneficial to educate family members about smoking cessation and the psychological, physiological, and behavioral changes that can occur with cessation. The family can also be counseled about what types of behaviors can undermine rather than support the nicotine dependence treatment effort. Family members can also assist and support the smoker in complying with treatment, for example, attending group meetings or encouraging the patient to call the physician, rather than discontinuing treatment, if adverse effects result from pharmacotherapy. The presence of one or more active smokers in the household may also need to be addressed, as this factor predicts relapse.

Some smokers may not be able to achieve successful abstinence with outpatient treatment despite intensive multiple interventions. Inpatient treatment represents a drastic intervention that should be reserved for the most treatment-resistant patients who have been completely unsuccessful despite repeated attempts and treatment with a variety of interventions. Inpatient treatment can provide the most intensive and aggressive program of treatment interventions coupled with close monitoring and prevention of access to nicotine. It requires a commitment of both time and money, however, as almost no insurance policies reimburse for such treatment. Inpatient nicotine dependence treatment is usually 1 week in duration. Follow-up data from the few programs in existence suggest that it may be effective for some highly treatment-resistant smokers (Hurt et al. 1992, Docherty 1991).

Special Considerations in Treatment

Co-occurring Mental Illness or Other Addictions

Individuals with nicotine dependence and either a co-occurring mental illness, another addiction, or all three are more likely to require some modifications in the traditional nicotine treatment approach. A critical issue in the treatment planning is the timing of the nicotine dependence treatment. There is literature supporting treating all together and also in delaying the nicotine dependence treatment until the other problems are stabilized. Successful nicotine dependence treatment in persons with active alcohol dependence is less likely than in individuals recovering from alcohol dependence, however, a few addiction treatment programs have addressed both problems simultaneously with success. Nicotine replacement appears to be especially beneficial in helping smokers with co-occurring mental illness and addiction. Appropriate treatment of the mental illness or other addiction is also important, including appropriate medications and therapy approaches. These individuals often benefit from clinicians beginning with a motivational enhancement approach that enhances the smoker’s readiness to change and self-efficacy (Steinberg et al. 2004). Adding BT may address the social and other skills deficits that are often present in persons suffering from these co-occurring problems (Hughes 1993b). There is a growing literature supporting that treatment can
be effective with these harder to treat smokers when motivational enhancement, NRT medications, psychiatric medications, and BTs are integrated (Ziedonis et al. 1998, American Psychiatric Association 1996). Several authors summarize ways to modify and integrate medication and BT approaches for use among smokers with schizophrenia (Ziedonis and George 1997, Hughes and McHugh 1995), with depression (Hall et al. 1998), and with substance use disorders (Bobo 1989, Clemmey et al. 1997, Istvan and Matarazzo 1984). Successful nicotine dependence treatment has been shown in several studies to be associated with successful recovery from alcohol dependence (Friend and Pagano 2005, Hughes 1993a, 1993b, Burling and Ziff 1988, Budney et al. 1993, Sellers et al. 1987) although one notable study—inconsistent with the existing literature indicated that although offering tobacco and alcohol dependence treatment concurrently ensures that a greater number of patients are reached, this strategy may have an adverse effect on alcohol abstinence when compared to delaying nicotine dependence treatment (Joseph et al. 2004). The dose of the transdermal patch was reduced from 21 mg during the first month to 14 mg during the second month and finally to 7 mg during the third month. Because he was apprehensive about discontinuing the 7 mg patch, he met with his physician to discuss his fears about relapse and ways of coping with situations he thought might be difficult. The patch was continued for an additional month, after which Mr. N was able to maintain successful abstinence. One year later, he called his physician after having relapsed. Because he had been smoking less than a pack of cigarettes per day for only 2 weeks, he was placed on 7 mg dose patch for only 2 weeks, after which the patch was discontinued. He discussed with his physician how a stressful family crisis had caused him to feel depressed and anxious, which he believed led to the relapse. He worked on coping skills and developing an alternative plan for handling bigger emotional triggers in the future. He was able to again successfully stop smoking and remained abstinent.

Clinical Vignette 1

A 55 year-old married physician, Dr. X, decided to finally talk to his primary care provider about smoking cessation strategies. He had smoked up to 2 packs per day for more than 30 years. For a long time he thought he could “quit any time” and considered smoking “just a habit,” making him “feel good, smart and more alert in the morning.” He discarded the growing scientific evidence about the addictive properties of nicotine and appeared comfortable with the concept that “it did not apply to me.” He also was slow to associate the reported negative health consequences of smoking to his own person. He ended up talking to his patients about smoking and increased risks for cardiovascular disease, respiratory pathology and malignancies because the information in the professional literature that he regularly read was quite compelling. This fact did not seem to change his cigarette use though. His family became more assertive in pointing out to him his chain smoking, the fact that he would light the first cigarette in the morning even before getting out of bed and that would “have to do it” where ever he was, during his daily professional activities, at home or while on vacation. He started to finally cut down on smoking at home when his teenage son provided him with scientific evidence about the significance of second-hand exposure. He was caught off guard when realizing the increased anxiety, irritability, agitation, headache, fatigue and very poor concentration when “accidentally” running out of cigarettes even for half a day. His best friend, a psychiatrist, was quick to explain the above symptomatology as nicotine withdrawal and to talk about “obvious dependence after so many years of smoking.” The veil of denial was beginning to tear but Dr. X, a proud, hard-working and highly respected medical professional decided to “try to beat this on my own.” Asking for help from the substance abuse and mental health community seem hard due to his strongly moralistic views about addiction as “lack of will power.” He switched to brands of low nicotine containing cigarettes; he tried cutting down on the number of daily cigarettes and he even applied aversive techniques, like smoke holding and rapid smoking. He was never able to achieve any sustained smoke-free periods of more than 3–4 weeks.

Clinical Vignette 2

A 55 year-old married physician, Dr. X, decided to finally talk to his primary care provider about smoking cessation strategies. He had smoked up to 2 packs per day for more than 30 years. For a long time he thought he could “quit any time” and considered smoking “just a habit,” making him “feel good, smart and more alert in the morning.” He discarded the growing scientific evidence about the addictive properties of nicotine and appeared comfortable with the concept that “it did not apply to me.” He also was slow to associate the reported negative health consequences of smoking to his own person. He ended up talking to his patients about smoking and increased risks for cardiovascular disease, respiratory pathology and malignancies because the information in the professional literature that he regularly read was quite compelling. This fact did not seem to change his cigarette use though. His family became more assertive in pointing out to him his chain smoking, the fact that he would light the first cigarette in the morning even before getting out of bed and that would “have to do it” where ever he was, during his daily professional activities, at home or while on vacation. He started to finally cut down on smoking at home when his teenage son provided him with scientific evidence about the significance of second-hand exposure. He was caught off guard when realizing the increased anxiety, irritability, agitation, headache, fatigue and very poor concentration when “accidentally” running out of cigarettes even for half a day. His best friend, a psychiatrist, was quick to explain the above symptomatology as nicotine withdrawal and to talk about “obvious dependence after so many years of smoking.” The veil of denial was beginning to tear but Dr. X, a proud, hard-working and highly respected medical professional decided to “try to beat this on my own.” Asking for help from the substance abuse and mental health community seem hard due to his strongly moralistic views about addiction as “lack of will power.” He switched to brands of low nicotine containing cigarettes; he tried cutting down on the number of daily cigarettes and he even applied aversive techniques, like smoke holding and rapid smoking. He was never able to achieve any sustained smoke-free periods of more than 3–4 weeks.
The withdrawal symptoms and intense cravings were instantaneously relieved by relapse. He even attempted contingency management by making abstinence dependent on certain amounts of money given to his best friend; it again did not work. He was about to give up on fighting against the nicotine dependence when his recurring exercise-related chest discomfort and leg pain were diagnosed as ischemic coronary pathology and peripheral vascular disease. These 2 medical conditions were added to preexisting hypertension, “borderline” elevation in the cholesterol levels and frequent bouts of bronchitis. This is the moment when reluctantly Dr. X turned to his primary care physician and asked for help. Dr. X explained that based on his readings he identified himself as being in the action stage of change. He expressed his disbelief at motivational enhancement or cognitive-behavioral psychotherapeutic approaches as well as the usefulness of support groups but was willing to try nicotine-replacement therapy. He wanted the nicotine gum because he thought he would have more control over its use and as he put it “would have something to do with my hands and mouth as if I were smoking.” He was instructed to choose a quit date when he would switch from smoking to the use of the gum. He was prescribed the 4-mg gums, presented their potential risks and benefits and explained the crunch and park procedure for their use. He was warned not to exceed 16 gums a day. He was also recommended to follow-up weekly for the first month after he stopped smoking to monitor for side effects, dose adjustments and overall progress. The withdrawal symptoms returned promptly following the quit date. Dr. X used the gums quite intensely exceeding “occasionally” the maximum number and reporting irritation in the mouth, nausea and dyspepsia. He admitted to “some benefit” but after 2–3 weeks he thought the cravings were “unbearable.” Dr. X requested to be switched to the patch in the hope of minimizing the fluctuations in the nicotine level. He was started on 21 mg and to his surprise he started feeling “somewhat better.” On occasion the urges to smoke were significant but overall he started noticing improvements in irritability, anxiety, fatigue and poor concentration. He surprised himself when he decided to ask his primary care physician for information on self help groups and relapse prevention techniques. He was still hoping to overcome the addiction on his own but seem to realize the need to extend the range of available skills and supports. It was around this time that during a business trip he developed prolonged precordial chest pain and collapsed. A massive inferior myocardial infarction was diagnosed complicated by treatment refractory arrhythmias. An emergent 5-vessel coronary artery bypass grafting was performed. The recovery period was prolonged. His cardiologist discontinued the nicotine patch during the attempts to stabilize the brittle cardiac rhythm abnormalities. After 6 weeks of rehabilitation efforts Dr. X returned home. He reported recurring cravings for cigarettes triggered by a multiplicity of factors. Buspar and Clonidine (the latter also added to control his fluctuating blood pressure) seem to do very little. Eventually he was prescribed Wellbutrin in a dose gradually increased to 300 mg daily. Over the following month Dr. X admitted to declining urges, irritability and “overall tension.” Persistent initial insomnia responded to Ambien. His appetite for sweets increased gradually and to his dismay the weight started to go up. Six months later Dr. X returned to work. He was free of chest pain and hemodynamically stable. He was still taking Wellbutrin and proudly talking about “being smoke-free.”

Chapter 62 • Substance Abuse: Nicotine Dependence

Nides M, Oncken C, Gonzales D, et al. (2006) Smoking Cessation with Varenicline, a Selective α4β2 Nicotinic Receptor Partial Agonist: Results from a 7-Week, Randomized, Placebo- and Bupropion-Controlled Trial with 1-Year Follow-up. Archives of Internal Medicine 166, 1561–1568.

Introduction

The term opioids describes a class of controlled substances that act on opioid receptors, are widely used to control pain, and have significant abuse liability though some can also be used to treat opioid dependence. Numerous opioid receptors have been identified, but the physiologic and pharmacologic responses in man are best understood for the mu (μ) and kappa (κ) receptors. The μ receptor, for which morphine is a prototypical agonist, appears to be the one most closely related to opioid analgesic and euphorogenic effects. Opioids can be natural substances such as morphine, semisynthetics such as heroin, and synthetics with morphine-like effects such as meperidine. In addition to pain control, these drugs are prescribed as anesthetics, antidiarrheal agents, or cough suppressants. In addition to morphine and heroin, the opioids include codeine, hydromorphone, methadone, oxycodone, and fentanyl among others. Drugs such as buprenorphine, a partial agonist at the μ receptor, and pentazocine, an agonist–antagonist, are also included in this class because their physiologic and behavioral effects are mediated through opioid receptors. Their abuse liability is partly a function of potency and method of administration; these characteristics for some drugs of this class are summarized in Table 63–1.

The opioids approved for medical use with the greatest abuse potential are under Schedule II of the CSA; examples include fentanyl, hydromorphone, methadone, morphine, and oxycodone.

Opioid-Related Disorders

As with other substances, there are two general categories of opioid-related disorders: opioid use disorders and opioid-induced disorders. Opioid use disorders include dependence and abuse (First and Pincus 2000). Opioid dependence, like other substance use disorders, has two sets of specifiers: the first being with physiologic features (i.e., tolerance and/or withdrawal), the second being with or without physiologic features. The second set describes course specifiers: early full remission, early partial remission, sustained full remission, sustained partial remission, on agonist therapy, and in a controlled environment. As of this writing, the agonist therapy category is used only with regard to the treatment of opioid dependence, and not in the treatment of other opioid-related disorders or substance dependencies.

Opioid-induced disorders include opioid intoxication, opioid withdrawal, opioid intoxication delirium, opioid intoxication psychotic disorders, opioid intoxication mood disorders, opioid intoxication sexual dysfunction, opioid intoxication sleep disorder, and opioid withdrawal sleep disorder. The defining features, according to DSM-IV-TR, for opioid dependence, abuse, intoxication, and withdrawal are similar to those for other substance use disorders. Essentially, opioid dependence is a cluster of cognitive, behavioral, and physiological symptoms indicating that the person is using high doses of opioids in a compulsive manner, for no legitimate medical reason, with loss of control over use and adverse medical or psychiatric consequences. Unlike...
Opioids emerged as a significant problem in Russia (Krupitsky et al. within this class in western countries and has more recently. Heroin has traditionally been the subject of most attention Dependence Epidemiology of Opioid Abuse and

cocaine, hallucinogens, solvents, and other substances that do not always produce withdrawal signs and symptoms, opioid dependence is almost always accompanied by significant physiological tolerance and a defined withdrawal–abstinence syndrome. Opioid abuse is a less severe disorder that consists of intermittent use of one or more opioids, in the absence of compulsive use and significant tolerance and/or withdrawal, but resulting in recurrent social, legal, or personal problems, or in use that is physically hazardous. Opioid intoxication consists of clinically significant maladaptive behaviors or psychological changes that are associated with acute opioid effects. Opioid withdrawal is a syndrome associated with abrupt cessation or reduction of opioid use in persons who have been taking opioids regularly and have developed neuroadaptation to their agonist effects. Opioid withdrawal symptoms are generally opposite those of intoxication.

Epidemiology of Opioid Abuse and Dependence
Heroin has traditionally been the subject of most attention within this class in western countries and has more recently emerged as a significant problem in Russia (Krupitsky et al. 2006a), Ukraine and other former Soviet States, Malaysia (Mazlan 2007), China, Iran (Mokri 2007), and Southeast Asia (Carrieri et al. 2006). In the US there has been a marked increase in prescription opioid abuse and dependence over the last 4–5 years such that it now has surpassed heroin. For example, the 2005 National Survey on Drug Use and Health (NSDUH; http://www.google.com/search?q=nsduh; accessed on 2/24/07) found that abuse or dependence on unprescribed pain relievers was 6.81 times more prevalent among persons aged 12 or older than abuse and dependence on heroin (see Figure 7.2 in NSDUH report). The overall number of persons meeting criteria for abuse or dependence on pain relievers was estimated at 1.55 million as compared to 227,000 abusing or dependent on heroin. It is unclear if a similar problem has emerged in other countries. Marijuana continued to be the most often abused substance in many countries including the US, with an estimated 4 million individuals according to a very recent national survey. However, in that same survey, first-time initiates of unprescribed pain relievers surpassed first-time users of marijuana, and past-year initiates of unprescribed pain relievers were 20.3 times more common than past-year initiates of heroin.

Heroin addiction has traditionally been associated with large urban areas in the US, especially in northeast and mid-Atlantic states; however, the increase in prescription opioid use has been more concentrated in suburban and rural areas (Smith and Woody 2005). Oxycodone and hydrocodone containing products have traditionally been the main prescription opioids of abuse. Much attention has focused on Oxycontin®, a long-acting formulation of oxycodone that contains doses up to 80 mg/tablet. Though the slow absorption of this medication is unlikely to result in abuse when taken as prescribed, substance abusers have discovered that the tablets can be crushed, freeing much of the oxycodone that can then be inhaled or injected to produce a potent euphoria. Vigorous efforts to identify the scope of the prescription opioid abuse problem and reduce its prevalence have been under way. These efforts may be having an effect because the last 2 years have seen a leveling off in the growth of this problem (see Table 2.2 in NSDUH report).

In addition to treatment programs specifically designed for substance use disorders, patients with opioid-related disorders are seen throughout the medical treatment system including private practice, emergency rooms, and consultation and liaison settings. Physicians practicing in penal institutions see large numbers of persons with opioid use disorders due to their association with high levels of criminal activity. Accidents and injuries due to violence associated with buying or selling drugs are common and patients with opioid-related disorders are frequently seen on trauma and surgical services. In some areas violence accounts for more opioid-related deaths than overdose or HIV infection.

Etiology and Pathophysiology of Opioid-Related Disorders
Opioid-related disorders, as in the case of other substance-related disorders, are felt to arise from a variety of social, psychological, and biological factors that interact to produce a “case.” Among those identified as especially important are
opioid use within the individual’s immediate social environment and peer group, availability of opioids, a history of childhood conduct disorder or adult antisocial personality disorder, and a family history of one or more substance use disorders. The families of persons with opioid dependence are likely to have higher levels of psychopathology, especially an increased incidence of alcohol and drug use disorders, and antisocial personality disorder (Rounsaville et al. 1982, Merikangas et al. 1998). These findings suggest that there is a genetic susceptibility to substance use disorders. Though many studies are underway to identify the nature and location of potential genetic factors for this susceptibility, the work is extremely complex (Mayer et al. 1997, Hohe et al. 2000) and clear findings are not available at this time nor is information on the influence of psychological and environmental factors on the expression of a presumed genetic predisposition.

The exact mechanism or mix of factors that produce opioid dependence or abuse are unknown, as are the factors that contribute to the chronic relapsing pattern that is typically seen in many of these patients. Studies by Dole and others suggest that persons who have used opioids regularly over extended periods of time experience physiological alterations as a consequence of chronic use that are permanent and which contribute to an inability to achieve periods of sustained remission (Dole and Nyswander 1965, Kreek 1986). The exact nature of these physiological alterations has not yet been identified. Studies by Wikler and others have demonstrated the existence of conditioned drug responses that can persist for years and which may contribute to relapse in formerly dependent individuals (Wikler 1980, O’Brien et al. 1997).

Intoxication

Opioid intoxication is characterized by maladaptive and clinically significant behavioral changes developing within minutes to a few hours after opioid use (see DSM-IV-TR criteria for substance intoxication). Symptoms include an initial euphoria sometimes followed by dysphoria or apathy. Psychomotor retardation or agitation, impaired judgment, and impaired social or occupational functioning are commonly seen. Intoxication is accompanied by pupillary constriction unless there has been a severe overdose with consequent anoxia and pupillary dilatation. Persons with intoxication are often drowsy (described as being “on the nod”) or even obtunded, have slurred speech, impaired memory, and demonstrate inattention to the environment to the point of ignoring potentially harmful events. Dryness of secretions in the mouth and nose, slowing of gastrointestinal activity, and constipation are associated with both acute and chronic opioid use. Visual acuity may be impaired as a result of pupillary constriction. The magnitude of the behavioral and physiologic changes depends on the dose as well as individual characteristics of the user such as rate of absorption, chronicity of use, and tolerance. Symptoms of opioid intoxication usually last for several hours, but are dependent on the half-life of the particular opioid that has been used. Severe intoxication following an opioid overdose can lead to coma, respiratory depression, pupillary dilatation, unconsciousness, and death (Table 63–2).

Withdrawal

Opioid withdrawal is a clinically significant, maladaptive behavioral and physiological syndrome associated with cessation or reduction of opioid use that has been heavy and prolonged (see DSM-IV-TR criteria for substance withdrawal). It can also be precipitated by administration of an opioid antagonist such as naloxone or naltrexone. Patients in opioid withdrawal typically demonstrate a pattern of signs and symptoms that are opposite the acute agonist effects. The first of these are subjective and consist of complaints of anxiety, restlessness, and an “achy feeling” that is often located in the back and legs. These symptoms are accompanied by a wish to obtain opioids (sometimes called “craving”) and drug-seeking behavior, along with irritability and increased sensitivity to pain. Additionally, patients typically demonstrate three or more of the following: dysphoric or depressed mood; nausea or vomiting; diarrhea; muscle aches; lacrimation or rhinorrhea; increased sweating; yawning; fever; insomnia; pupillary dilatation; fever; and piloerection. Piloerection and withdrawal-related fever are rarely seen in clinical settings (other than prison) as they are signs of advanced withdrawal in persons with a very significant degree of physiologic dependence; opioid-dependent persons with “habits” of that magnitude usually manage to obtain drugs before withdrawal becomes so far-advanced (Table 63–3).

</table>

For short-acting drugs such as heroin, withdrawal symptoms occur within 6–24 hours after the last dose in most dependent persons, peak within 1–3 days, and gradually subside over a period of 5–7 days. Symptoms may take 2–4 days to emerge in the case of longer acting drugs such as methadone. Less acute withdrawal symptoms are sometimes present and can last for weeks to months. These more persistent symptoms can include anxiety, dysphoria, anhedonia, insomnia, and drug craving.

Dependence

Opioid dependence is diagnosed by the signs and symptoms associated with compulsive, prolonged self-administration of opioids that are used for no legitimate medical purpose, or if a medical condition exists that requires opioid treatment, are used in doses that greatly exceed the amount needed for pain relief (see DSM-IV-TR criteria). Persons with opioid dependence typically demonstrate continued use in spite of adverse physical, behavioral, and psychological consequences. Almost all persons meeting criteria for opioid dependence have significant levels of tolerance and will experience withdrawal upon abrupt discontinuation of opioid drugs. Persons with opioid dependence tend to develop such regular patterns of compulsive use that daily activities are typically planned around obtaining and administering drugs.

Opioids are usually purchased on the illicit market, but they can also be obtained by forging prescriptions, faking or exaggerating medical problems, or by receiving simultaneous prescriptions from several physicians. Physicians and other health care professionals who are dependent will often obtain opioids by writing prescriptions or by diverting opioids that have been prescribed for patients.

Abuse

Opioid abuse is a maladaptive pattern of intermittent use in hazardous situations (driving under the influence, being intoxicated while using heavy machinery, working in dangerous places, etc.), or periodic use resulting in adverse social, legal, or interpersonal problems (see DSM-IV-TR criteria). All of these signs and symptoms can also be seen in persons who are dependent; abuse is characterized by less regular use than dependence (i.e., compulsive use not present) and by the absence of significant tolerance or withdrawal. As with other substance use disorders, opioid abuse and dependence are hierarchical and thus persons diagnosed as having opioid abuse must never have met criteria for opioid dependence.

Assessment and Clinical Picture

Opioid use disorders can occur at any age, including adolescence and the geriatric years, but most affected persons are between 20 and 45 years of age. There have been increasing numbers of reports of adolescents presenting for treatment with opioid problems, though good data are hard to find. Neonates whose mothers are addicted can experience opioid withdrawal, as will be discussed later. Rarely, young
Opioid Dependence
A maladaptive pattern of opioid use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

(1) Tolerance, as defined by either of the following:
   (a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect
   (b) markedly diminished effect with continued use of the same amount of the substance

(2) Withdrawal, as manifested by either of the following:
   (a) the characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the criteria sets for withdrawal from the specific substance)
   (b) the same (or a closely related) substance taken to relieve or avoid withdrawal symptoms

(3) The substance is often taken in larger amounts or over a longer period than was intended

(4) There is a persistent desire or unsuccessful efforts to cut down or control substance use

(5) A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance, or recover from its effects

(6) Important social, occupational, or recreational activities are given up or reduced because of substance use

(7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance

Specify if:
With physiological dependence: evidence of tolerance or withdrawal (i.e., either Item 1 or 2 is present)
Without physiological dependence: no evidence of tolerance or withdrawal (i.e., neither Item 1 nor 2 is present)

Abuse
A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

(1) Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)

(2) Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)

(3) Recurrent substance-related legal problems

(4) Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for substance dependence for this class of substance.
use. Females commonly have disturbances of reproductive function and irregular menses.

**Laboratory Findings.** During dependence, routine urine toxicology tests are often positive for opioid drugs and remain positive for most opioids for 12–36 hours. Methadone, because it is longer acting, can be identified for several days. Fentanyl is not detected by standard urine tests but can be identified by more specialized procedures. Oxycodeone, hydrocodone, and hydromorphone are often not routinely included on urine toxicology tests though they can be identified by some of these assays and by gas chromatography/mass spectrometry. Testing for fentanyl is not necessary in most programs, but needs to be performed in assessing and treating health care professionals such as anesthesiologists, persons working in intensive care or pain management units who have access to this drug. Concomitant laboratory evidence of other abuseable substances such as cocaine, marijuana, alcohol, amphetamines, and benzodiazepines is common.

Hepatitis screening tests are often positive, either for hepatitis B antigen (signifying active infection) or hepatitis B and/or C antibody (signifying past infection). Mild to moderate elevations of liver function tests are common, usually as a result of chronic infection with hepatitis C but also from toxic injury to the liver due to contaminants that have been mixed with injected opioids, or from heavy use of other hepatotoxic drugs such as alcohol. Low platelet count, anemia, or neutropenia, as well as positive HIV tests or low CD-4 cell counts are often signs of HIV infection. HIV is commonly acquired via the practice of sharing injection equipment, or by unprotected sexual activity that may be related to the substance use disorder, for example, exchanging sex for drugs or money to buy drugs.

**Differential Diagnosis.** Individuals who are dependent on “street” opioids are usually easy to diagnose due to the physical signs of intravenous use, drug-seeking behavior, reports from independent observers, the lack of medical justification for opioid use, urine test results, and the signs and symptoms of intoxication or withdrawal.

The signs and symptoms of opioid withdrawal are fairly specific, especially lacrimation and rhinorrhea, which are not associated with withdrawal from other abuseable substances. Other psychoactive substances with sedative properties such as alcohol, hypnotics, or anxiolytics can cause a clinical picture that resembles opioid intoxication. A diagnosis can usually be made by the absence of pupillary constriction, or by the lack of response to a naloxone challenge. In some cases, intoxication is due to opioids along with alcohol or other sedatives. In these cases, the naloxone challenge will not reverse all of the sedative drug effects.

Difficult diagnostic situations are seen among persons who fabricate or exaggerate the signs and symptoms of a painful illness (such as kidney stones, migraine headache, back pain, etc.). Because pain is subjective and difficult to measure, and because some of these individuals can be very skillful and deceptive, diagnosis can be difficult and time-consuming. Drugs that are obtained in such deceptions may be used by the individual in the service of his/her dependence or abuse, or may be sold on the illicit drug market for profit. These individuals cause problems not only for physicians, but also for patients with disorders that need opioids for pain relief. Patients who have pain that should be treated promptly with opioids are sometimes denied treatment or given inadequate amounts of opioids due to uncertainty or disbelief about the legitimacy of their complaints. Patients with cancer, kidney stones, or other painful conditions have sometimes suffered considerably from this type of “reverse discrimination.” An example of an individual with drug-seeking behavior is given in Clinical Vignette 1.

**Clinical Vignette 1**

The medical director of a health care organization (HMO) referred a 43-year-old male for evaluation/treatment of pain. He had been receiving Percocet on a regular basis (4/day) for the last 2 years from an internist for chronic pain secondary to kidney problems. Prior to his referral, he had been in and out of emergency rooms over the past 6 years for treatment of renal pain. He had been prescribed narcotic analgesics on numerous occasions and his health plan had been billed for his care. As a result, the HMO had limited treatment to only his internist, and refused to pay for any care unless it was approved in advance. Review of his medical records revealed that he had been thoroughly worked-up for kidney disease on several occasions, and that he had an A-V malformation with periodic bleeding and clot formation; he had also passed kidney stones on at least two occasions. A cystoscopy done previously had showed evidence of traumatic lesions in the wall of the bladder that were secondary to instrumentation. Social and occupational history showed that he had worked at two hospitals and on one occasion had impersonated a psychologist. During previous employment he had improperly used a company vehicle. When his supervisor attempted to have him fired, he turned the proceedings around and almost had the supervisor fired for failing to follow proper administrative procedures. Currently, he was working as an administrative aide for the city courts, and was in a hurry to “get his prescription filled” so that he could return to work. He described some of the problems he had experienced in attempting to obtain “proper treatment” from the HMO and expressed annoyance that he had been referred to the drug program for evaluation. He was very concerned about confidentiality, and felt that people he knew might see him entering the program and think that he had a drug problem. During the initial interview, he described his contacts in government, implying that he would not hesitate to complain if his treatment was inadequate or unsatisfactory. Upon examination he was well dressed, in no acute distress, and superficially friendly. There were no signs of anxiety, depression, loose associations, or of homicidal or suicidal ideas. His mood was in a normal range and his affect was appropriate, though it seemed as if he could become angered easily if frustrated or provoked. There were no overt signs or symptoms of opioid withdrawal or intoxication. After examination and based on the history, it was decided to give him a trial of methadone for pain and a dose of 20 mg was administered. Over the next hour the patient was observed to become sleepy with his speech slurred and rambling; respiratory and heart rates were mildly depressed and his pupils were constricted, all symptoms of opioid intoxication. Later, the patient admitted that he had not been using the Percocets; in fact, he had sold them for extra “spending money.”
Persons with opioid dependence will often present with psychiatric signs and symptoms such as depression or anxiety. Such subjective distress often serves to motivate the patient to seek treatment and thus can be therapeutically useful. These symptoms can be the result of opioid intoxication or withdrawal, or they might result from the pharmacological effects of other substances that are also being abused such as cocaine, alcohol, or benzodiazepines. They may also represent independent, nonsubstance-induced psychiatric disorders that require long-term treatment. The correct attribution of psychiatric symptoms that occur in the context of opioid dependence or abuse follows the principles that are outlined in the substance-related section and other relevant parts of DSM-IV-TR.

Opioids are much less likely to produce psychopathology than most other drugs of abuse, and in some instances they reduce psychiatric symptoms such as anxiety and associated depression. In these cases, symptoms will emerge not during opioid use, but after it is discontinued. Clinicians have observed this problem in methadone maintenance patients who occasionally have an exacerbation of symptoms of schizophrenia, posttraumatic stress disorder (PTSD), or other problems during or following a methadone dose taper.

**Course and Natural History of Opioid Dependence**

Opioid dependence can begin at any age, but problems associated with opioid use are most commonly first observed in the late teens or early 20s. Once dependence occurs it is usually continuous over a period of many years even though periods of abstinence are frequent. Reoccurrence is common even after many years of forced abstinence, such as occurs during incarceration. Increasing age appears to be associated with a decrease in prevalence. This tendency for dependence to remit generally begins after age 40 and has been called “maturing out.” However, others remain opioid dependent into their 50s or 60s and beyond. Thus, though spontaneous remission can and does occur, most cases of untreated opioid dependence follow a chronic, relapsing course for many years.

**Treatment**

There are currently a number of effective pharmacological and behavioral therapies for the treatment of opioid dependence, with these two approaches often combined to optimize outcome. There are also some newer options, which may take various forms. For example, methadone maintenance is an established treatment, while the use of buprenorphine and buprenorphine/naloxone in an office-based setting represents a relatively new variation on that theme. Clonidine has been used extensively to treat opioid withdrawal while lofexidine is a structural analog that appears to have less hypotensive and sedating effects. The depot dosage form of naltrexone, available in the US currently for the treatment of alcohol dependence and under development for opioid dependence treatment, may increase compliance with a medication that is a highly effective opioid antagonist but which has been underutilized due to poor acceptance by patients. In almost every treatment episode using pharmacotherapy, it is combined with some type of psychosocial or behavioral treatment. Recent research has documented the value of these additional treatments and provided insight into those that are the most effective, as discussed later in more detail.

**Detoxification: Long-Term, Short-Term, Rapid, and Ultra-Rapid**

Detoxification from opioids, for most patients, is only the first phase of a longer treatment process. Most patients seeking treatment have been addicted to heroin or other opioids for 2–3 years, and some for 30 years or more. Thus, treatment usually involves changes in individuals’ lifestyles. Though generally ineffective in achieving sustained remission unless combined with long-term pharmacological, psychosocial, or behavioral therapies, detoxification alone continues to be widely used. It is sometimes the only option available for individuals who do not meet criteria for, do not desire, or do not have access to agonist or partial agonist medications such as methadone or buprenorphine.

The detoxification process may include use of opioid agonists (e.g., methadone), partial agonists (e.g., buprenorphine), antagonists (e.g., naloxone, naltrexone), or nonopioid alternatives such as clonidine, benzodiazepines, or nonsteroidal anti-inflammatory agents. In many cases, one or more medications are combined, such as naloxone with clonidine and a benzodiazepine (Table 63–4). The choice of detoxification medication and the duration of the process depend on numerous factors including patient preference, clinician expertise and experience, type of treatment facility, licensing, and available resources. Ultimately, however, the goal of detoxification is the achievement (and maintenance) of a drug-free state while minimizing withdrawal. Unfortunately, detoxification for some individuals appears to be used as an expedient means to achieve a drug-free state rapidly with no follow-up pharmacological or behavioral therapy.

Opioid detoxification paradigms are frequently categorized according to their duration: long-term (typically 180 days), short-term (up to 30 days), rapid (typically 3–10 days), and ultra-rapid (1–2 days). These temporal modifiers provide only a coarse description of the paradigm; they do not provide other important information such as the medications used or whether postdetoxification pharmacological, psychosocial, or behavioral therapy is provided. However, some general guidelines typically apply.
The most common detoxification protocols, and those for which the best data are available, are the long-term (typically 180 days) and short-term (up to 30 days) paradigms involving the use of methadone. Unfortunately, these strategies have not generally been associated with acceptable treatment response using relapse to opioid use as an outcome criterion. For example, one study (Banys et al. 1994) reported that more than half of the individuals participating in a 180-day detoxification program were using opioids illicitly during the medication taper phase. Six-month follow-up indicated that 38.5% of the urine samples (n = 26) tested negative for illicit opioids, only 3 of 31 patients reported remaining free of illicit opioids for the entire 6 months prior to follow-up, and 22 participated in some other form of treatment (Reilly et al. 1995). Results from more rapid detoxification using short- or even intermediate-term (up to 70 days) medication-tapering protocols are even less encouraging and have an unfortunately low success rate. It should be noted, however, that provision of additional services such as counseling, behavioral therapy, treatment of underlying psychopathologies, job skills training, and family therapy to address concomitant treatment needs can improve outcome though success rates remain low, even with these services (Kleber 1999).

Rapid detoxification involves the use of an opioid antagonist, typically naltrexone or naloxone, in combination with other medications (such as clonidine and benzodiazepines) to mitigate the precipitated withdrawal syndrome. The procedure is intended to expedite and compress withdrawal in order to minimize discomfort and decrease treatment time. Ultra-rapid detoxification also utilizes other medications, along with an opioid antagonist, to moderate withdrawal effects. However, rather than individuals being awake as they are during the rapid detoxification process, they are placed under general anesthesia or, alternatively, deeply sedated. A comprehensive review of the rapid and ultra-rapid detoxification literature has been published (O’Connor and Kosten 1998). Rapid detoxification studies were conducted in inpatient facilities, outpatient substance abuse treatment settings, and outpatient primary care facilities; ultra-rapid ones were confined to inpatient settings. Patients included those who were heroin dependent as well as those in methadone maintenance treatment. Only four of the ultra-rapid detoxification studies reviewed provided follow-up beyond the initial detoxification. Retention on postdetoxification naltrexone maintenance in one study was 53% at 1 month and 82% in another at 3 months.Only one of the ultra-rapid detoxification studies provided follow-up information indicating that all individuals were taking naltrexone 30 days post detoxification. Another study (Hensel and Kox 2000) in which ultra-rapid detoxification was followed by naltrexone maintenance and supportive psychotherapy, indicated that 49 of 72 patients were opioid abstinent 12 months following detoxification. All of these studies involved self-selected individuals, thus making it impossible to know the overall effectiveness of this type of intervention.

A major concern regarding ultra-rapid detoxification is the occurrence of potentially serious adverse effects, such as respiratory distress (San et al. 1995), or other pulmonary and renal complications (Pfib et al. 1999) during or immediately following the procedure. A high frequency of vomiting has also been reported (Cucchia et al. 1998). The degree to which serious adverse events occur has not yet been determined; however, there have been reports of sudden death occurring shortly after the procedure that were not caused by relapse to opioid use and overdose (O’Brien et al. [2001] personal communication).

In spite of the emerging evidence about serious adverse events, ultra-rapid detoxification may be appropriate for highly selected individuals based on considerations of previous treatment history, economic factors, and patient choice. However, patients seeking this treatment must be thoroughly informed that serious adverse events, including sudden unexpected deaths, have occurred in association with this procedure and its use should probably be limited to inpatient settings where monitoring by anesthesiologists and other highly trained staff is available.

Buprenorphine, a μ-opioid partial agonist, has also been used as a detoxification agent. Results from early inpatient studies have shown that it is safe, well tolerated, and mitigates opioid withdrawal signs and symptoms over a range of doses and detoxification schedules (Cheskin et al. 1994, Parran et al. 1994, Vignau 1998) and in outpatients (O’Connor et al. 1997, Diamant et al. 1998). More recent studies have confirmed and extended those findings. In particular, they have demonstrated the comparative efficacy of buprenorphine to clonidine or lofexidine, two alpha-adrenergic agonists (White et al. 2001, Oreskovich et al. 2005, Ponizovsky et al. 2006). One trial that utilized ancillary treatment medications and standard counseling procedures was conducted in community treatment programs (Ling et al. 2005). It involved both inpatient and outpatient participants and demonstrated a significant benefit of buprenorphine over clonidine with regard to the study’s criterion for treatment success; the proportion of participants who were both retained in the study for its duration and provided an opioid-free urine sample on the last day of attendance. Another study, unique in that it compared buprenorphine to clonidine in a 28-day medical detoxification program for adolescents, found that buprenorphine was associated with better treatment retention and a greater percentage of opioid-negative urine samples (Marsch et al. 2005). Clonidine has been shown to suppress many of the autonomic signs and symptoms of opioid withdrawal. It can cause sedation and hypotension but has been used with few problems when appropriate monitoring is available. It does not suppress the subjective discomfort of withdrawal and probably for that reason is not well accepted by most patients.

Other alpha-2-adrenergic agonists have also been evaluated in order to find agents that are as or more effective, but less sedating and hypotensive than clonidine. Lofexidine, a medication that was originally promoted as an antihypertensive but was shown to lack clinically significant hypotensive effects, has been the most studied. When compared to clonidine, it has been found to equally suppress autonomic signs and symptoms of opioid withdrawal but with less sedation and hypotension (Kahn et al. 1997, Lin et al. 1997, Carnwath and Hardman 1998). When compared to methadone dose tapering, lofexidine detoxification was associated with opioid withdrawal effects that peaked sooner, but resolved to negligible levels more rapidly (Bearn et al. 1996). In another study (Bearn et al. 1998), an accelerated 5-day lofexidine treatment regimen attenuated opioid withdrawal symptoms more rapidly than 10 days of either lofexidine or methadone, with similar blood pressure responses observed.
for the lofexidine groups. Data regarding the potential effectiveness of guanabenz and guanfacine have also been reported, but further studies are required to assess the potential utility of these medications. In summary, recent studies have shown that lofexidine is likely to be a useful opioid detoxification agent whose efficacy approximates that of clonidine but with fewer side effects.

**Opioid Agonist Pharmacotherapy**

Methadone maintenance was developed by Dole and Nyswander (1968) and has become the most commonly used pharmacotherapy for opioid dependence. Methadone acts at the μ-opioid receptor and its ability to suppress opioid withdrawal for 24–36 hours following a single oral dose makes it an ideal medication for this purpose. Another μ-opioid agonist, LAAM, received approval in the US for maintenance treatment in 1993 and in Europe. LAAM is a long-acting congener of methadone that suppresses withdrawal for 48–72 hours and thus has the advantage of requiring less frequent clinic visits than methadone, which must be taken daily. Though it has been shown effective, it was taken off the market in Europe because it was reported to have caused a few deaths due to prolongation of the QT interval. Only one company was manufacturing it and as a result of the European experience, the company stopped making it and it is no longer available, though it is still approved in the US. A third medication, buprenorphine (and a combination of buprenorphine with naloxone), received approval in the US for opioid dependence treatment in 2002 and has been used extensively in France. It has been mentioned previously as a detoxification agent and will be discussed later and in more detail as it has unique pharmacological properties compared to other therapeutic agents.

Both methadone and LAAM are Schedule II controlled substances and in the US can only be used for maintenance and detoxification in programs that are licensed by the Drug Enforcement Administration (DEA) and must pass periodic inspections to make certain that they are in compliance with national accrediting organizations and local requirements. The regulations in countries where methadone is allowed typically specify who is eligible for treatment, procedures that are required for its administration, the number of take-home doses permitted, and the type of medication storage security needed. Treatment programs in the US have been inspected at periodic intervals for the past 40 years and violations have resulted in sanctions ranging from administrative citations to, in a very limited number of cases, criminal prosecution in response to very serious problems. This combination of regulation by law enforcement and other agencies has resulted in a treatment system that is separated from the mainstream of other medical care and that consists almost entirely of specially licensed and inspected clinics in the US. Efforts were made to correct this problem in 2000 when the FDA transferred responsibility for inspecting methadone programs to State and other authorities. However, many clinics continue to be located in buildings that have been converted to comply with regulations but that were never intended for medical use. At the present time, it is estimated that approximately 240,000 patients are being maintained on methadone at 1,000 or more sites in the US (Parrino [2006] personal communication); this number represents 10–20% of all persons with opioid dependence based on data from the 2005 NHSDA, where 1.8 million persons were estimated to meet criteria for opioid abuse or dependence on prescription opioids or heroin. Use of methadone is also common in most European countries, Australia, and is rapidly expanding in Iran and China; buprenorphine is used more often than methadone in France (Carrieri et al. 2006).

The appropriate dose of agonist medication has been a subject of federal and local regulations in most countries, though there has been a gradual shift toward allowing more clinical judgment in its determination, especially in the US. A number of studies have been done during the last 35 years to determine the optimal dose and, although it is clear that some patients do well on low doses of methadone, studies have consistently shown that most individuals need higher doses if they are to achieve maximum benefit from agonist treatment (Ball and Ross 1991). The results of these comparison studies are generally supportive of the guidelines originally proposed by Dole and Nyswander, who recommended doses in the 80–120 mg/day range (Dole and Nyswander 1968). Clear relationships between methadone blood levels and clinical response have not been observed consistently. One study found significant correlations between oral dose and methadone concentration, but only among patients who complained of low dosing (Hiltunen et al. 1999). These findings suggest that some patients may be more sensitive to dose changes and that clinical response, including subjective complaints, is a more important guide to adequate dosing than blood levels. No controlled studies have been done examining doses above 120 mg even though they have become more common in the last several years due to the increased potency of heroin in many areas; thus the upper limits of dosing effectiveness are not well understood.

In addition to the transfer of regulatory oversight in the US from the FDA to State and other local authorities, there was another major paradigm shift in the way that opioid replacement pharmacotherapy can be provided, beginning with passage of the Drug Addiction Treatment Act of 2000 (DATA 2000). This legislation allowed for the use of CSA Schedule III, IV, and V medications for treatment of opioid dependence by physicians who have received a waiver from the Center for Substance Abuse Treatment of the Substance Abuse and Mental Health Services Administration. Secondly, the FDA approved the use of buprenorphine and a buprenorphine/naloxone combination product for that indication. Thus, these two products can now be used outside the confines of traditional opioid treatment programs (OTPs) through what is commonly referred to as the office-based opioid treatment (OBOT) paradigm. Additionally, both buprenorphine and buprenorphine/naloxone may be used in OTPs as well. Initially, a limit of 30 patients per practice, and then 30 patients per prescriber, capped the maximum number of patients that a physician could treat at any one time in OBOT. Most recently, in December 2006, an amendment to the Controlled Substance Act enabling qualified physicians to treat up to 100 patients with buprenorphine and buprenorphine/naloxone was signed by the President (H.R. 6344 [2006]). It is anticipated that this recently passed legislation will enable more individuals to access treatment for opioid addiction.

To qualify for the waiver under DATA (2000) as described above, a physician must meet any one or more
of certain criteria (Substance Abuse and Mental Health Services Administration 2007). Some of these criteria include the following:

- Holding a subspecialty board certification in addiction psychiatry from the American Board of Medical Specialties.
- Holding an addiction certification from the American Society of Addiction Medicine.
- Holding a subspecialty board certification in addiction medicine from the American Osteopathic Association.
- Having, with respect to the treatment and management of opioid-addicted patients, completed not less than 8 hours of training (through classroom situations, seminars at professional society meetings, electronic communications, or otherwise) that is provided by the American Society of Addiction Medicine, the American Academy of Addiction Psychiatry, the American Medical Association, the American Osteopathic Association, the American Psychiatric Association, or any other organization that the Secretary determines is appropriate for purposes of this subclause.

Although buprenorphine has been available internationally as an analgesic for approximately 30 years, it has only been available as an opioid addiction treatment medication for approximately 10 years, with approval first coming in France in 1996. Currently, over 40 countries have approved buprenorphine and/or buprenorphine/naloxone for the treatment of opioid dependence. Unlike methadone, which is a full opioid agonist at the μ receptor, buprenorphine is a partial μ agonist and also an antagonist at the κ receptor (Martin et al. 1976, Sadée et al. 1982). As such, buprenorphine administration is associated with effects that are dose dependent within a limited range, but that are submaximal at higher doses. This ceiling to the effects of buprenorphine provides for a greater margin of safety (e.g., with regard to respiratory depression) than that of full μ agonists. Additionally, buprenorphine has a high affinity for the μ-opioid receptor and dissociates slowly from it, thus attenuating the severity of withdrawal (Villiger and Taylor 1981, Rothman et al. 1995).

Since buprenorphine undergoes extensive first-pass metabolism after oral administration, it is administered sublingually as an opioid addiction pharmacotherapy. It is available in the US in both 2-mg and 8-mg dosages strengths. The buprenorphine/naloxone combination product, which was developed to reduce potential diversion and misuse, contains each component in a 4:1 ratio; 2 mg/0.5 mg and 8 mg/2 mg sublingual tablets are available. Naloxone is only poorly absorbed when administered sublingually. Thus, if a buprenorphine/naloxone sublingual tablet is crushed and administered parenterally by an opioid-dependent individual, the naloxone component is likely to precipitate an opioid withdrawal syndrome, which potentially could serve as a deterrent to further abuse. Individuals may be inducted onto therapy with either buprenorphine or buprenorphine/naloxone, but the latter should be used for unsupervised (e.g., take-home) administration unless the combination product cannot be tolerated due to the above properties that are hoped to reduce its potential for abuse as compared to buprenorphine alone (the “mono product”).

Buprenorphine is metabolized to norbuprenorphine primarily by cytochrome P-450 3A4 (Iribarne et al. 1997). Thus, the concomitant use of 3A4 inducers such as azole antifungal agents, macrolide antibiotics, and HIV protease inhibitors may potentially be associated with increases in buprenorphine plasma levels that could result in signs and symptoms of overmedication. Conversely, the concomitant use of 3A4 inducers (e.g., phenobarbital, phenytoin) has the potential to decrease plasma levels of buprenorphine to subtherapeutic levels, although this interaction has not been systematically evaluated. Given the relatively higher incidence of HIV disease in the addict population compared to the general one, it is fortuitous that there appear to be few potentially significant drug interactions between buprenorphine and HIV/AIDS treatment medications. For example, efavirenz has been associated with a pharmacokinetic, but not pharmacodynamic, interaction with buprenorphine when used clinically (McCanne-Katz 2005). On the other hand, the combination of ritonavir and atazanavir with buprenorphine has been reported to be associated with an adverse event profile that has necessitated an adjustment to the buprenorphine dose, perhaps as a consequence of decreased metabolism of buprenorphine to norbuprenorphine and decreased formation of buprenorphine glucuronide (Bruce and Altice 2006).

It is likely that the most important potential interaction is the combination of buprenorphine with benzodiazepines, alcohol, and/or other CNS depressants. In a preclinical study (Nielsen and Taylor 2005), the combination of a benzodiazepine with buprenorphine was found to modify the ceiling effect observed when buprenorphine was administered alone, making buprenorphine appear to be more like a full agonist. Thus, the potential for severe respiratory depression may be increased when these medications are combined. Although the concomitant use of buprenorphine and benzodiazepines is not contraindicated, it is prudent to limit the prescribing of buprenorphine with CNS depressants generally. When the combination of buprenorphine and other CNS depressants cannot be avoided, it is important to monitor patients more closely for adverse events such as excessive sedation and respiratory depression.

**Antagonist Maintenance**

Naltrexone is the prototypical opioid antagonist used in abstinence therapy, blocking the effects of heroin and other opioids through competitive receptor inhibition. Naltrexone has no opioid agonist effects and is a competitive opioid antagonist. It is orally effective and can block opioid effects for 24 hours when administered as a single daily oral dose of 50 mg; oral doses of 100–150 mg can block opioid effects for 48–72 hours (Lee et al. 1998). Opioid addicts in the US and most western countries have not favored naltrexone despite a favorable adverse event profile (nausea is typically the most common side effect), though interest and adherence have been much better in Russia (Krupitsky et al. 2006b) and in persons under significant legal pressure to stop opioid use (Cornish et al. 1998). Possible reasons for nonadherence and lack of interest are that unlike opioid agonists and partial agonists, it produces no positive, reinforcing effects nor does it attenuate the protracted opioid abstinence syndrome that can persist for several weeks after detoxification. Furthermore, it may precipitate an opioid withdrawal syndrome if
used too soon after opioid use stops, an effect that can be minimized by administering a naloxone challenge prior to giving the first dose of naltrexone.

While there is an extensive literature spanning more than 35 years on naltrexone treatment, work continues on increasing adherence and improving outcomes. One approach has been to combine it with family therapy and contingency management, which have improved adherence somewhat (Fals-Stewart and O’Farrell 2003), and contributed to the positive findings from studies in Russia where family members helped encourage adherence (Krupitsky et al. 2006b). Another has been to develop depot forms that block opioid effects for 14–28 days or longer. The only depot currently approved in the US is Vivitrol (http://www.vivitrol.com), which is injected once a month and approved for treatment of alcohol dependence. A naltrexone implant that blocks opioid effects for 6 months has been developed by Australian researchers and used with apparent success in several thousand opioid-dependent patients, though it has not completed the steps necessary for approval (http://www.staplefordcentre.co.uk/naltrexone-implants.htm). A Russian company has also developed an implant that blocks opioid effects for 2 months and is approved for use in that country (prodetoxon@mail.ru). These depot forms provide more time for patients to overcome their typical ambivalence about stopping opioid use and could result in more long-term success than has been the case with oral naltrexone. Another variant on antagonist treatment is nalmefene, an orally effective but somewhat longer acting (about 48 hours at dosages of 50–100 mg/day) opioid antagonist that has been effective for alcohol treatment (Mason et al. 1994) and shows promise as an alternative to naltrexone for opioid dependence (Jones et al. 2000).

**Psychosocial/Behavioral Treatments**

Recent research has called attention to the fact that, as in other substance use disorders, most patients with opioid dependence and abuse are ambivalent about stopping use, as mentioned above (Miller and Rollnick 1991, Rollnick et al. 1999). This ambivalence presents a challenge as it contributes to varying levels of motivation to enter and remain in treatment, to early dropout, and to partial or (in some cases) nontreatment response. Studies have emphasized that clinicians must be aware of this “normal” ambivalence, and make reasonable efforts to resolve it in favor of sustained treatment participation and cessation of use (Rollnick et al. 1999). Suggestions that have been made regarding initial steps to maximize the chances for engagement in treatment and cessation of drug use include avoiding unnecessary delays in accessing treatment, expressing a hopeful and nonjudgmental attitude, performing a comprehensive evaluation, and developing a treatment plan that is responsive to patients’ self-identified goals (Miller and Rollnick 1991).

In addition to challenges related to ambivalence, patients often have serious problems with nonopioid substance abuse and/or with medical, psychiatric, legal, employment, and family/social issues that preexist or result from the addiction. Research has found that addressing these additional problems can be helpful (McLellan et al. 1993), particularly if done on site (Umbricht-Schneiter et al. 1994); however, these approaches require coordination of services from multiple disciplines and are not always feasible.

**Individual Drug Counseling**

The most common type of psychosocial treatment in opioid agonist maintenance is individual drug counseling. Counselors are typically persons at the masters or bachelors level who deliver a behaviorally focused treatment aimed to identify specific problems, help the patient access services that may not be provided in the clinic (e.g., medical, psychiatric, legal, family/social), stop substance use, reduce HIV risk, and improve overall adjustment. Functions that counselors perform include monitoring methadone doses and requesting changes when needed, reviewing urine test results, responding to requests for take-home medication, assisting with family problems, responding to crises, writing letters for court or social welfare agencies, recommending inpatient treatment when necessary, and providing support and encouragement for a drug-free lifestyle.

Counseling usually addresses both opioid and nonopioid use and their associated behaviors. Although nicotine (tobacco) use is not always included, the increased emphasis on adverse health effects of smoking has resulted in more attention to stop smoking at all levels within substance abuse treatment programs, including drug counseling. Counselors and patients typically have weekly, 30- to 60-minute sessions during the first weeks or months of treatment with reductions in frequency to biweekly or monthly depending on progress. The frequency of counseling can vary widely depending on the severity of the patient’s problems, clinic requirements, and counselor workload.

The importance of regular counseling was clearly demonstrated in a study by McLellan et al. (1993) in which patients were randomly assigned to minimal counseling (one 5- to 10-minute session per month), standard counseling (one 45-minute session per week), or enhanced counseling (standard plus on-site referral to psychiatric, medical, and family/social services). Results showed a dose–response relationship with the minimal condition doing significantly worse than standard, and enhanced counseling doing the best overall; however, about 30% of patients did well with only minimal counseling. This study clearly demonstrated the positive benefits achieved by drug counseling and showed that, for most patients, counseling is necessary to maximize the benefits of agonist maintenance.

Though most counseling is individual, some programs use group therapy exclusively and others do not use it at all. Most agonist programs that use groups have them only for patients with focal problems such as HIV disease, PTSD, homelessness, or problems with grief following loss of close personal relationships. Many programs encourage patients to participate in self-help groups but advise them to select a group that accepts persons who are on agonist maintenance. Some programs have self-help groups that meet on site. Counselors, like psychotherapists, can vary widely in the results they achieve (McLellan et al. 1988). This variability seems more related to the ability to form a positive, helping relationship than to specific techniques (Luborsky et al. 1985).

Contingency management techniques are always included in drug counseling, if for nothing else but to fulfill regulations about requiring progress in treatment as a condition of providing take-home doses, and studies have shown that such contingencies can be helpful. For example, an opportunity to receive take-home doses in return for
Drug-free urine tests is a powerful and practical motivator for many patients (Iguchi et al. 1996). More flexibility in dispensing take-homes for positive behavior could be an additionally useful result of the regulatory reforms that were described earlier. Another contingency that is easily applicable and which some programs have used with positive results is requiring a negative alcohol breath test prior to dispensing the daily dose of methadone.

Though counseling and other services are effective enhancements of agonist treatment, compliance is often an issue and clinics vary in the way they respond to this problem. Some remind patients of appointments, others do not permit patients to be medicated unless they keep appointments, and others suspend patients who miss appointments. For noncompliant patients, a powerful contingency is requiring certain behaviors for patients to remain on the program, a procedure that is often formalized in a “treatment contract.” Here, the patient is given the option of stopping heroin and other drug use, keeping regular appointments, looking for work, or correcting other behaviors that need improvement as a condition for remaining in treatment. Patients who fail are administratively detoxified, suspended for months to years, and referred to another program, although the referrals are not always successful.

The long-term effects of this type of contingency management have not been well studied. For example, relatively little is known about negative effects on patients who might have improved with methadone and counseling, but not to the degree required by the contingency, and are subsequently discharged for failing a contract. A study done in Philadelphia (Zanis and Woody 1998) found that among 110 patients who were administratively discharged or dropped out of a Veterans Affairs maintenance program, 8.2% (9/110) died within the following year as compared to only 1% (4/397) who remained in treatment. Among the 43 patients (from the 110) who were discharged for failing a treatment contract, 5 (11.6%) died within a year. None of these five were in treatment at the time of death and all died as a result of overdoses. No overdose deaths occurred among patients remaining in treatment and, interestingly, there were no deaths in those who were suspended for violating program rules (mainly drug dealing or giving a false urine specimen). These results have been replicated in a later study (Woody et al. 2007) and are consistent with other studies showing higher rates of mortality among opioid-dependent individuals who are not in methadone treatment as compared to those who are on methadone. A representative of these studies was done in New South Wales, Australia, where it was found that only 3% of the 953 heroin-related fatalities occurred among patients receiving methadone maintenance (Darke et al. 1996). These data emphasize the dangers of suspension from maintenance treatment if the alternative is no treatment. These data, when considered along with studies showing a protective effect of maintenance on acquiring HIV infection (Metzger et al. 1998), have made some clinicians increasingly hesitant to suspend patients from maintenance treatment for positive urine test results alone.

This caution may be especially relevant in environments where the potency of heroin is high and the risk of serious adverse events among those who are suspended is substantial unless they are enrolled in an alternative and meaningful treatment.

Therapeutic Communities (TCs)
These programs are another approach that has been useful for treating persons with opioid dependence, especially those with a long history of addiction and a strong motivation to become drug free, either as a result of their own wish to recover, or from external pressures such as being given the choice of entering a TC or being incarcerated for a drug-related crime. These programs are very selective, self-governing, and long term (6–18 months), and take place in residential settings where patients share responsibilities for maintaining the milieu (cleaning, cooking, and leading group therapy). Confrontation of denial and behaviors such as lying and “conning,” combined with group support for healthy, positive change, is used to restructure character and the addictive lifestyle. Medications such as methadone or naltrexone are rarely used, though many programs have adopted buprenorphine for detoxification. Medications for psychiatric or medical conditions are usually available after careful screening and evaluation. Many TCs have large numbers of individuals who have been referred by the criminal justice system including some who have not responded well to agonist maintenance on repeated occasions. Though dropout rates are high, studies have shown that over 80% of individuals who complete TCs have a sustained remission and demonstrate significant improvement in psychiatric symptoms, employment, and criminal behavior (Inciardi et al. 1997, DelLeon 1999).

Addressing Comorbidity
Patients seeking treatment for opioid dependence are typically using one or more other substances (cocaine, alcohol, benzodiazepines, amphetamines, marijuana, nicotine), and have additional problems in the psychiatric, medical, family/social, employment, or legal areas. In fact, it is rare to find a person with only opioid dependence and no other substance use, or without a psychiatric, medical, or family/social problem. The presence of these problems, perhaps with the exception of nicotine dependence, tends to magnify the severity of the opioid dependence and makes the patient even more difficult to treat. An example of successful treatment of a difficult patient is given in Clinical Vignette 2.

Clinical Vignette 2
A 42-year-old male presented for treatment of opioid dependence; this was his sixth episode of methadone maintenance. The patient had a long history of alcoholism that interfered with treatment in the past and had begun using cocaine regularly. The patient had done fairly well in the past on methadone as far as illicit opioid use was concerned, but clinic attendance and his ability to comply with clinic rules, especially regarding take-home doses, had been severely compromised by alcohol abuse. The patient would typically remain in treatment for about a year, then become angry over his inability to obtain take-home doses due to ongoing positive breathalyzer readings, and drop out of treatment; relapse to opioid use always immediately followed. During previous treatment episodes, the patient had frequently been offered inpatient detoxification for alcoholism but always refused because (1) “alcohol was not his problem, heroin was the problem” and (2) he could not take time off work. When the patient presented for...
treatment this time, he had severe social stressors; was unemployed (secondary to his alcohol problems) and living with his parents, who were threatening to put him out because of drug use.

He was told that this time, methadone would not be offered unless he first entered the hospital. After some discussion, he agreed that as part of his treatment plan he would first enter the hospital for 21–28 days of treatment including alcohol detoxification and stabilization on methadone and then be discharged to maintenance therapy. This approach worked. After inpatient discharge, the patient kept regular counseling appointments, continued to attend self-help meetings to which he had been introduced while on the inpatient unit, “requested” daily breathalyzer testing, and turned down an offer to return to his job in the liquor store. Over the past 3 years, his liver function tests returned to normal levels, he was stable on 65 mg of methadone/day with urine tests negative for opioids, although occasionally his urine was positive for cocaine.

**Psychiatric**

Among the psychiatric disorders seen in persons with opioid dependence, antisocial personality is one of the most common (First and Pincus 2000). Diagnostic studies of persons with opioid dependence have typically found rates of antisocial personality disorder ranging from 20 to 50%, as compared to less than 5% in the general population. PTSD is also seen with increased frequency.

Opioid-dependent persons are especially at risk for the development of brief depressive symptoms, and for episodes of mild to moderate depression that meet symptomatic and duration criteria for major depression or dysthymia. These syndromes represent both substance-induced mood disorders as well as independent depressive illnesses. Brief periods of depression are especially common during chronic intoxication or withdrawal, or in association with psychosocial stressors that are related to the dependence. Insomnia is common, especially during withdrawal; sexual dysfunction, especially impotence, is common during intoxication. Delirium or brief, psychotic-like symptoms are occasionally seen during opioid intoxication (First and Pincus 2000).

The data on psychiatric comorbidity among opioid addicts and its negative effect on outcome (McLellan et al. 1983) have stimulated research on the effect of combining psychiatric and substance abuse treatment. Among these have been studies showing that tricyclic antidepressants can be useful for chronically depressed opioid-dependent persons who are treated with methadone maintenance (Nunes et al. 1998). Two other studies have shown that professional psychotherapy can be useful for psychiatrically impaired, methadone-maintained opioid addicts (Woody et al. 1984, 1999), although similar results were not found in a related study done in a different setting (Rounsaville et al. 1983). The main result in most pharmacotherapy and psychotherapy studies with methadone-maintained addicts has usually been a reduction in psychiatric symptoms such as depression, and a less consistent effect on reductions in substance use (Nunes et al. 1998, Woody et al. 1985, 1995).

Less than 5% of persons with opioid dependence have psychotic disorders such as bipolar illness or schizophrenia; however, these patients can present special problems since programs typically have few psychiatric staff. As a result, these patients are sometimes excluded from methadone treatment because they cannot be effectively managed within the constraints of the available resources. Others are treated with methadone, counseling, and the same medications used for nonaddicted patients with similar disorders. Though studies evaluating the outcome of combining opioid agonist treatment with antipsychotic or antimanic medications have not been done, there is little controversy that these medications are useful for persons with opioid dependence and psychotic disorders.

Women with opioid dependence can present special challenges because many have been sexually abused as children, have other psychiatric disorders, and are involved in difficult family/social situations (Blume 1999). Abusive relationships with addicted males are common, sometimes characterized by situations in which the male exerts control by providing drugs. These complex psychiatric and relationship issues have emphasized the need for comprehensive psychosocial services that include psychiatric assessment and treatment, and access to other medical, family, and social services. A promising treatment approach entitled “Seeking Safety” has been developed to address problems of substance abuse and PTSD (http://www.seekingsafety.org), and is being tested in a randomized trial in the National Institute on Drug Abuse Clinical Trials Network at the time this writing.

**Medical**

Medical comorbidity is a major problem among persons with opioid dependence; HIV infection, AIDS, and hepatitis B and C have become some of the most serious and common problems, especially hepatitis C. Sharing injection equipment including “cookers” and rinse water, or engaging in high-risk sexual behaviors are the main routes of infection. Sexual transmission appears to be a more common route of HIV transmission among females than males because HIV is spread more readily from males to females than from females to males. Females who are intravenous drug users and engage in prostitution or other forms of high-risk sex are at extremely high risk for HIV infection (Blume 1999). Cocaine use has been found to be a significant risk factor as a single drug of abuse or when used in combination with heroin or other opioids (Booth et al. 2000).

After rising rapidly in the late 1970s and early 1980s, the incidence of new HIV infections among intravenous drug users, of whom opioid-dependent individuals constitute a large proportion, has decreased (Seage et al. 2001). However, as a result of high levels of needle sharing and other risky behavior in the early phases of the epidemic, HIV infection rates are as high as 60% in some areas of the US. Due to the long incubation period prior to the development of AIDS, it is expected that future years will continue to see high levels of morbidity and mortality associated with HIV, although the advent of new pharmacotherapies for HIV has extended many lives.

Studies have identified several important interactions between methadone and drugs to treat HIV. However, information is not complete and more studies are needed to map out the full extent of these interactions. One important interaction is that methadone increases plasma levels of zidovudine. The associated symptoms resemble methadone withdrawal and there have been instances in which...
methadone doses have been increased in response to complaints of withdrawal, with the dose increases compounding the problem. Another important interaction involves decreased methadone levels secondary to nevirapine that may result in mild to moderate withdrawal. This interaction can be important if the patient is taken off either of these two drugs while on methadone, since the result may be a sudden rise in methadone levels with signs and symptoms of over medication (Altice et al. 1999, Otero et al. 1999).

As mentioned earlier, opioid-related mortality is high; studies have found annual death rates among opioid-dependent individuals of 10 per 1,000 or greater, which is substantially higher than demographically matched samples in the general population (Gronbladh et al. 1990). Common causes of death are overdose, accidents, injuries, and medical complications such as cellulitis, hepatitis, AIDS, tuberculosis, and endocarditis. The cocaine and alcohol dependence that is often seen among opioid-dependent persons contributes to cirrhosis, cardiomyopathy, myocardial infarction, and cardiac arrhythmias.

Tuberculosis is a particularly serious problem among intravenous drug users, especially heroin addicts. In most cases, infection is asymptomatic and evident only by the presence of a positive tuberculin skin test. However, many cases of active tuberculosis have been found, especially among those with HIV.

Other medical complications of heroin dependence are seen in children born to opioid-dependent women. Perhaps the most serious is premature delivery and low birthweight, a problem that can be reduced if the mother is on methadone maintenance and receiving prenatal care (Finnegan 1991). Another is physiological dependence on opioids, seen in about half the infants born to women maintained on methadone or dependent on heroin or other opioids. Effective treatments for neonatal withdrawal are available and long-term adverse effects of opioid withdrawal have not been demonstrated. Buprenorphine has theoretical advantages to methadone for treating neonatal withdrawal because of its partial agonist effects and relatively mild withdrawal syndrome, though it is not approved for that indication. Adverse neonatal effects associated with buprenorphine have not been observed when it has been used, and studies are currently underway to determine its safety and efficacy for use in pregnancy and neonatal withdrawal.

A recent study found that methadone is present in the breast milk of women maintained on doses as high as 180 mg but that the concentration is very low and no adverse effects were observed in the infants (McCarty and Posey 2000). HIV infection is seen in about one-third of infants born to HIV-positive mothers, but can be reduced to about 10% if HIV-positive pregnant women are given zidovudine prior to delivery (Connor et al. 1994). HIV can also be transmitted by breast feeding, and thus formula is recommended for HIV-positive mothers. In the exception of countries where it is unavailable or unaffordable. Thorough washing of infants born to HIV-infected mothers immediately after delivery also appears to reduce the incidence of HIV infection.

Integrated Treatment
The comorbidity data have led to research that has demonstrated positive effects from integrating psychiatric and medical care within agonist and other substance abuse treatment programs, so-called one-stop shopping (Kessler et al. 1996). Clinical experience and National Institute on Drug Abuse demonstration projects have shown that integration of services can be done with very positive results on adherence to recommended medical treatments and evaluations (Umbricht-Schneiter et al. 1994). Related to this line of research are studies that have shown improved compliance with directly observed antituberculosis pharmacotherapy (Chaulk et al. 1995). These findings have important implications for tuberculosis control in methadone programs since intravenous drug users are at high risk for tuberculosis infection and because maintenance programs are settings where directly observed therapy can be easily applied. Similar principles apply to administration of psychotropic medication in noncompliant patients with schizophrenia or other major Axis I disorders.

Harm Reduction
Harm reduction is concerned with minimizing negative consequences of addiction. As such, a focus is placed on the consequences of use and its attendant behaviors (Marlatt 1996). Examples of harm reduction include needle exchange programs, efforts directed at reducing drug-use-associated behaviors that may result in the transmission of HIV, and making changes in policies (including increasing treatment availability) that reduce heroin use and the criminal behavior associated with drug procurement. Harm reduction is not only to reducing harm to the individual addict, but also to family, friends, and to society generally. Other terms sometimes used synonymously with harm reduction include harm minimization, risk reduction, and risk minimization (Riley et al. 1999).

A number of authors have identified the limitations of harm reduction when it is used as a sole strategy to combat the adverse effects of addiction. For example, Reuter and Caulkins (1995) point out the benefit of balancing drug use reduction and harm reduction components into a single framework, since reducing either component is likely to lower the chances for harm. Roche et al. (1997) have proposed a model for an integrated addiction treatment strategy that incorporates harm reduction and use reduction with abstinence and nonuse, in addition to other critical elements such as factors related to culture and gender. Additionally, MacCoun (1998) has provided a template for integrating harm reduction with prevalence reduction (discouraging the engagement in drug use) and quantity reduction (encouraging the reduction in frequency or extent of drug use).

With regard to opioids, much of the health-related harm from their improper or illicit use is secondary to elements other than the substances themselves (Kalant 1999). Sequelae from unhygienic methods of administration and poor injection technique are typically more serious than the constipation or other side effects of the drugs themselves, acute overdoses notwithstanding. At current levels of use, greater harm in the overall population of most countries is expected to result from the use of alcohol and tobacco rather than from opioids. With regard to opioid addiction treatment, maintenance on methadone or buprenorphine may be considered harm reduction measures. Both have the potential to reduce morbidity, mortality, and crime associated with drug use and the addict lifestyle and in this sense their outcomes
on target symptoms of opioid dependence bear a resemblance to the results of other medical therapies that control but do not cure the underlying problem, such as treatments used for hypertension, diabetes, or asthma.

Nasal/syringe exchange has been one of the most controversial strategies for harm reduction. Research indicates that these programs may have beneficial effects in a number of areas, including a reduction in the spread of blood-borne infections such as hepatitis and HIV, and acting as a conduit to more comprehensive drug-abuse treatment services (Normand et al. 1995). In one study (Bluthenthal et al. 2000), the initiation and continuation of participation in a syringe exchange program by high-risk injection drug users was independently associated with a cessation of syringe sharing. In another (Strathdee et al. 1999), participation in a needle exchange program was associated with individuals entering detoxification treatment for both HIV-infected and noninfected groups. Not all findings have been positive, however. In a study designed to assess the association between risk behaviors and HIV infection among injection drug users, risk elevations for HIV associated with needle exchange programs were substantial and consistent despite adjustment for confounding factors (Bruneau et al. 1997). However, an examination of potential bias in nonrandomized comparisons (Hagan et al. 2000) suggested that injection drug users participating in needle exchange programs at a given point in time might include a high proportion of individuals whose pattern of drug use puts them at greater risk for blood-borne viral infections. Further, a prospective cohort study found no evidence of a causal association between needle exchange program participation and transmission of HIV (Schechter et al. 1999).

Harm reduction related to psychoactive substance abuse has gone through a number of stages. The current phase has been described as the development of an integrated public health perspective for all drugs in which a multifaceted, strategic approach is taken (Erickson 1999). Some of the most recent approaches have been the studies of daily, observed heroin administration for addicts who are unwilling to engage in the existing treatments or who have continued regular heroin use while on methadone maintenance. The first of these studies was done in Switzerland, followed by the Netherlands and Germany. Results have been positive (Blanken et al. 2005) and similar studies are now being considered or implemented in other countries. The direction of this approach will be guided, in part, by whether biases against a harm reduction philosophy can be overcome by those who see it as synonymous with acceptance of drug abuse or legalization, and how harm reduction objectives relate to an overall strategy to improve public health.

Sedative–hypnotics include a chemically diverse group of medications primarily prescribed for treatment of anxiety, panic disorders, sleep disturbances and seizure disorders. They may be misused and their use can result in development of a substance use disorder abuse or dependence with physiological dependence. Inadequately treated, withdrawal of sedative–hypnotics may be life-threatening.

Considerations of sedative–hypnotic use disorders should reflect a sensible balance between their medical uses, and abuse and dependence. A discussion of the broad range of medical applications of sedative–hypnotics is beyond the scope of this chapter. This chapter focuses on adverse consequences of sedative–hypnotic use and the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) (American Psychiatric Association 2000) criteria of abuse and dependence.

Alcohol could be viewed as a sedative–hypnotic; however, alcohol, because of its widespread use and different cultural role in society is generally considered separately. Buspirone, although marketed for the treatment of anxiety, has a pharmacological profile sufficiently different that it is not usually included among the sedative–hypnotics. Antidepressant, anticonvulsants, and antihistamines have clinically useful antianxiety properties in some situations, but are not discussed here because they are not generally associated with abuse and dependence. Likewise Ramelteon, a hypnotic whose mechanism of action involves the melatonergic system (Owen 2006), does not appear to be associated with abuse and dependence. The medications traditionally included in the category of sedative–hypnotics are listed in Table 64–1.

With the exception of the benzodiazepines and newer hypnotics (e.g., zaleplon, zopiclone, eszopiclone, and zolpidem), overdose with sedative–hypnotics can be lethal. Benzodiazepines and the newer hypnotics are rarely lethal if taken alone; in combination with alcohol or other drugs, however, they can be lethal.

When the benzodiazepines were introduced into clinical medicine in the early 1960s, their lack of lethality in overdose led physicians to believe that they were without harmful effects. Over time, it was recognized that the benzodiazepines could produce severe physiological dependence (American Psychiatric Association Task Force on Benzodiazepine Dependency 1990) and could be drugs of abuse. Nonetheless, their medical utility in treatment of disabling anxiety, episodic sleep disturbances, and seizures has made them indispensable to medical practice. The utility of this class of medication has led to the development of newer sedative–hypnotic drugs that are as clinically effective as benzodiazepines, but with a reduced dependence and tolerance liability.

Table 64–1  Sedative–Hypnotic Medications

*Flunitrazepam and zopiclone are not marketed in the US.

Sedative–Hypnotic Related Disorders

Drug abuse, misuse, and addiction are deeply rooted in social values and attitudes. These social values in mainstream culture are reflected in drug abuse policy and drug control laws. For example, moderate use of alcohol is widely sanctioned for adults, but public intoxication or driving with an alcohol blood level above 80–100 mg/dL is not.

The term “misuse” is commonly applied to prescription sedative–hypnotics. The DSM-IV-TR does not provide criteria for misuse as it does for abuse and dependence. When medications are taken in higher doses, more frequently or for a longer period than prescribed, or taken by someone other than the person for whom the medication was prescribed, the behavior is generally considered misuse of the medication.

DSM-IV-TR defines abuse and dependence in terms of behavioral and physiological consequences to the person taking the medication. The criteria for abuse and dependence are intended to apply as uniformly as possible across classes of drugs, and the criteria do not distinguish the source of the medication or the intended purpose for which it was originally taken. Further, when most people, including physicians speak of drug dependence, they are referring to physical dependence, as characterized by aversive physiological consequences and symptoms that arise during withdrawal. DSM-IV-TR uses the term dependence to denote a more severe form of substance use disorder than abuse, and it uses specifiers “with physiological dependence” or “without physiological dependence” to note the presence or absence of physical dependence. Physiological dependence is not required for a diagnosis of drug dependence. A diagnosis of substance dependence is made when a patient has dysfunctional behaviors that are a result of the drug use, and demonstrates an inability to modify or curb their use despite the often negative consequences of these behaviors.

Establishing whether or not the dysfunctional behavior is the “result” of drug use is extremely important. The patient may need to be observed medication-free to determine whether dysfunction is “caused” by drug use. The patient, the patient’s family members and the treating psychiatrist may disagree about what is causing symptoms or behavioral dysfunction. Likewise, the underlying motivation for “drug-seeking” behavior may vary. For example, a patient whose panic attacks are ameliorated by a medication may exhibit what may be interpreted as drug-seeking behavior if access to the medication is threatened.

Sedative–Hypnotics and GABA Receptors

GABA is the major inhibitory neurotransmitter in the central nervous system (CNS) mediating inhibition at three different classes of receptors designated as GABA_A, GABA_B, and GABA_C. (Loh and Ball 2003, Johnston et al. 2003). The GABA_A receptor, a ligand-gated chloride ion channel or ionophore, contain binding sites for neurosteroids, benzodiazepines and barbiturates (Smith and Olsen 1995).

The opening or closing of the chloride channels affect the electrical polarization of a cell. Opening the chloride channel increases the inflow of chloride ions and increases the negative potential on the surface of the cell, thereby inhibiting firing of the cell.

The benzodiazepine receptor is allosterically coupled to the GABA_A receptor: occupation of the benzodiazepine receptor by benzodiazepine agonists enhances the efficacy of GABA at the GABA_A receptor. Likewise occupation of the GABA_A receptor by GABA increases the affinity of benzodiazepines for the benzodiazepine receptor (Klein et al. 1994).

Substances that bind to the benzodiazepine site and facilitate the opening of chloride channels are designated agonists, those that decrease the chloride channel opening are inverse agonists, and those which occupy the site with no effect are antagonist. GABA_A receptor composition can

1DSM-IV-TR page 195.
undergo significant changes in response to neurosteroids, barbiturates, benzodiazepines and alcohol, and to withdrawal of these substrates.

The benzodiazepine receptors, which are of primary concern here, are comprised of subunits, designated \( \alpha, \beta, \gamma, \) and \( \delta \). Receptors have different ratios of subunits and different subunit composition designated, for example, \( \alpha_1 \) or \( \alpha_2 \) etc. These differences have physiological significance, for example, \( \alpha_1 \) subunits confer benzodiazepine sensitivity; \( \alpha_4 \) and \( \alpha_6 \) subunits confer benzodiazepine insensitivity (Smith 2001).

Chronic administration of and withdrawal from benzodiazepines appear to alter gene expression and function of the GABA\(_A\) receptor, in vitro studies have found that benzodiazepine withdrawal can upregulate \( \alpha_4 \) subunits and downregulate \( \alpha_1 \) subunits making the GABA\(_A\) receptors less responsive to benzodiazepine receptor agonists (Follesa et al. 2001). This may explain in part why over time benzodiazepines appear to become less effective in controlling symptoms in some patients, which gives them an impetus to increase dosage (Lader 1994). A similar shift towards an increase in \( \alpha_4 \) containing GABA\(_A\) receptors and decreased benzodiazepine sensitivity has also been characterized as a component of ethanol withdrawal (Ma et al. 2004).

Hypnotic drugs such as zolpidem, zaleplon, eszopiclone, and zopiclone also bind to the benzodiazepine site on GABA\(_A\) receptors.

**Abuse and Abuse Potential**

Unlike drugs of abuse (e.g., methamphetamine or heroin) that are manufactured in clandestine laboratories and distributed through the street-drug black markets, sedative–hypnotics are exclusively manufactured by pharmaceutical companies. Sedative–hypnotics abused by addicts are acquired by Internet purchase, the drug black market, by robbery, or treatment subterfuge from physicians and pharmacies. Drug dependence may arise as an inadvertent consequence of medical treatment (iatrogenic) or through patient’s self-abuse of sedative–hypnotics. The prevalence of abuse of a particular sedative–hypnotic is to some extent a reflection of its accessibility through medical channels.

The usual data sources for monitoring the prevalence of drug use in the US (e.g., the National Household Survey of Drug Use) are not valid measures of dependence. The Drug Abuse Warning Network (DAWN), which measures mentions of drugs occurring in emergency rooms, is limited because the mentions of drugs can be confounded by appropriate medical use.

The term “abuse” can have different meanings depending on its context of use. DSM-IV-TR provides specific behavioral criteria for diagnosis of “abuse” of a specified drug. Abuse can also mean any nonmedical use, or use considered outside accepted medical practice. Recreational abuse of hypnotics is their use to produce intoxication or “a high” (Griffiths and Johnson 2005).

Some authors distinguish “recreational abuse” from “chronic quasi-therapeutic abuse,” which is characterized by long-term use of a drug that is inconsistent with medical practice or against medical advice (Griffiths and Johnson 2005).

Until recently, studies of hypnotic efficacy were usually structured in terms of a few weeks. In clinical practice, many patients used them for months to years. Practice standards generally specify that they should be used for short-term treatment of insomnia. A 6-month placebo-controlled study of eszopiclone (Lunesta) (Krystal et al. 2003), discussed later in more detail, provided evidence that tolerance to the hypnotic effects did not develop.

Most people do not find the subjective effects of sedative–hypnotics pleasant or appealing beyond their therapeutic effects (e.g., relief of anxiety or facilitation of sleep). Many sedative–hypnotic abusers, on the other hand, have a subjectively different response to sedative–hypnotics. Addict’s qualitative difference in subjective responses to medications is an important reason why medications that are safe and efficacious for nonaddicts cannot be safely prescribed for addicts. In addition, addicts may take doses of medications above recommended dosages, take them by injection or means other than prescribed (e.g., dissolving tablets and injecting them, crushing tablets and snorting them), or take them in combination with other prescription medications or street drugs such as heroin or cocaine, that put them at risk for adverse consequences.

Most individuals with sedative–hypnotic dependence are patients whose dependence evolved during a course of medical treatment, drug abusers (including alcohol) who also use sedative–hypnotics in addition to other drugs, or drug abusers who use sedative–hypnotics to self-medicate adverse effects of other drugs of abuse such as cocaine or methamphetamine.

The sedative–hypnotics discussed in this chapter all have some abuse potential, but there are differences in abuse potential between them. Some of the differences in abuse potential are mediated by their pharmacology, but often, access, current fashions, and availability all contribute.

Patients receiving methadone maintenance use benzodiazepines to “boost” (enhance) subjective effects of methadone. Some alcoholic patients use benzodiazepines either in combination with alcohol or as a second-choice intoxicant, if alcohol is unavailable. Fat-soluble benzodiazepines that enter the CNS quickly are usually the benzodiazepines preferred by addicts.

Addicts whose urine is being monitored for benzodiazepines prefer benzodiazepines with high milligram potency, such as alprazolam or clonazepam. These benzodiazepines are excreted in urine in such small amounts that they are often not detected in drug screens.

**Patterns of Abuse**

Some sedative–hypnotics, such as the short-acting barbiturates, are primary drugs of abuse—that is, they are injected for the “rush” or are taken orally to produce a state of disinhibition similar to that achieved with alcohol. Oral methaqualone was commonly used as a recreational drug. Most abuse of benzodiazepines is in the context of a poly-drug use pattern in which they are taken in combination with other primary intoxicants, such as alcohol or heroin, to intensify the desired subjective effects.

Drug abusers may also use sedative–hypnotics to self-medicate withdrawal of drugs such as heroin. When the avowed intent is to stop the use of drugs such as heroin,
physicians may be lured into thinking that addicts’ self-administration of sedative–hypnotics is not “abuse.” While on occasion this may be the case, often it is not. Addicts’ episodic attempts to stop using heroin by self-medicating opiate withdrawal symptoms with sedative–hypnotics without entering drug abuse treatment rarely results in opiate abstinence and may result in the secondary development of sedative–hypnotic dependence.

Addicts may also use sedative–hypnotics to reduce unpleasant side effects of stimulants, e.g., cocaine or methamphetamine. Impairment of judgment and memory produced by the sedative–hypnotic in combination with wakefulness of a stimulant may result in unpredictable behavior.

**Barbiturates**

During the late 1960s and early 1970s, the short-acting barbiturates, secobarbital and pentobarbital, were common drugs of abuse. Addicts dissolved the tablets or the contents of capsules in water and injected the solution. The desired effect was the “rush,” a dreamy, floating feeling lasting a few minutes after the injection. After the rush, the addict was intoxicated, but the primary appeal towards injection was the rush. The intoxication is not qualitatively different from that produced by oral ingestion of a short-acting barbiturate.

Injection of a barbiturate is associated with the usual infectious risk of injecting street drugs, but the barbiturates are particularly pernicious if inadvertently injected into an artery or if the solution is injected or leaked from a vein or artery into tissue surrounding the vessel. Barbiturates are irritating to tissue, and the affected tissue becomes indurated and may abscess. In addition, barbiturate solution injected into an artery produces intense vasoconstriction and blockage of the arterioles, resulting in gangrene of areas supplied by the artery.

**Methaqualone**

Methaqualone (Quaalude) was removed from the US market in 1984 because of its abuse. In many countries it was marketed under the brand name of Mandrax, a formulation of methaqualone (250 mg) and diphenyldramine hydrochloride (25 mg). Although methaqualone and its isomers were removed from the legal market in South Africa in 1971, it remained a popular drug of abuse among South African drug abusers at least through 2002. Detailed instructions for its synthesis are available on the Internet.

**Benzodiazepines**

For treatment of anxiety and insomnia, the benzodiazepines have largely supplanted the older sedative–hypnotics. The benzodiazepines have a major advantage over the older compounds. In an overdose, the older sedative–hypnotics are lethal at 10–15 times the usual therapeutic doses. Benzodiazepines, if taken alone, have a therapeutic ratio exceeding 100. In combination with alcohol or other drugs, the benzodiazepines may contribute to the lethality, but death from a benzodiazepine alone overdose is rare. Some atavistic uses of the older compounds remain driven primarily by economic considerations and misguided attempts to reduce abuse of benzodiazepines by addicts and perceived overprescription of benzodiazepines by physicians.

Benzodiazepines are often used or misused by addicts to self-medicate opiate withdrawal, to intensify the CNS effects of methadone, or to ameliorate the adverse effects of cocaine or methamphetamine.

Flunitrazepam, a potent benzodiazepine hypnotic never marketed in the US, is widely available by prescription in many other countries in 1- or 2-mg oral dosage forms and for injection. In the mid-1990s Rohypnol achieved notoriety as the date-rape drug. Because of the media attention, considerable public debate ensued and the US Congress was prompted to pass legislation increasing penalties for rape when Rohypnol or other drugs were used to facilitate it.

Flunitrazepam has many street names, including rophies, ropies, roopies, roiffies, rofines, rofinol, loops, and wheels (Calhoun et al. 1996). Tablets of Rohypnol have the name of the manufacturer Roche engraved on them and a number indicating the milligram strength (either 1 or 2). Drug abusers usually prefer the 2-mg tablets, which are often called “Roche dos” or just “Roche” (usually pronounced “row-shay”). Although flunitrazepam is similar in many respects to other benzodiazepines in abuse potential (Woods and Winger 1997), flunitrazepam is among the benzodiazepines with the highest abuse potential (Farre et al. 1996, Bond et al. 1994) and has considerable appeal among heroin addicts (Thirion et al. 2002, Salvaggio et al. 2000).

Flunitrazepam and other benzodiazepines have also been associated with deaths among opiate addicts taking buprenorphine in France (Reynaud et al. 1998, Tracqui et al. 1998). Although buprenorphine alone or benzodiazepines alone are rarely fatal, the combination appears to increase the lethality, presumably having synergistic action in suppressing respiration (Gueye et al. 2002).

**Nonbenzodiazepine Hypnotics**

The nonbenzodiazepine hypnotics, zolpidem, zaleplon, eszopiclone, and zopiclone are not chemically benzodiazepines but are similar in pharmacological profile. They bind to a portion of the benzodiazepine receptor site on the GABA_A receptor (Byrnes et al. 1992). They are replacing the benzodiazepines as the most commonly prescribed hypnotics and, like the benzodiazepines, are relatively nonlethal if taken alone in an overdose. These medications are sometimes referred to as a class in professional and lay publications as the “Z” drugs, or “Z” hypnotics, to distinguish

---

4Subsequently, GHB (gamma-hydroxybutyric acid), which has some properties of a sedative-hypnotic, was also called a “date-rape drug.”
them from the prebenzodiazepine hypnotics such as the barbiturates, chloral hydrate and methaqualone. The sedative effects (including respiratory depression) are reversed by the benzodiazepine antagonist flumazenil (Wesenstein et al. 1995).

Like the benzodiazepines, the medications are remarkably safe from an overdose perspective. If taken alone, they are usually not lethal even when ingested many times the usual therapeutic dose. Their abuse potential appears less than benzodiazepines such as diazepam and flunitrazepam. Sudden cessation of therapeutic doses can produce in some individuals a period of rebound insomnia and increase in dream intensity, but not seizures. Case reports of dependence usually involve marked dose escalation and withdrawal may resemble high-dose benzodiazepine withdrawal.

Zolpidem

Zolpidem (Ambien), an imidazopyridine hypnotic widely prescribed for treatment of insomnia, has been available for prescription since 1993 in the US and in Europe for several years before. It is commonly offered for sale by Internet pharmacies. A new product formulation, AmbienCR®, is widely advertised in professional journals and direct to consumer on TV and lay magazines. AmbienCR is a layered tablet with part of the tablet being rapidly released for sleep induction and a sustained release portion that is claimed to sustain sleep.

Case reports of abuse suggest that some patients increase the dosage many times above what is prescribed and that zolpidem produces a withdrawal syndrome similar to that of other sedative-hypnotics (Aragona 2000). The case histories also describe significant tolerance to the sedative effects of zolpidem.

Zolpidem is rapidly absorbed and has a short half-life (2.2 hours). Its sedative effects are additive with alcohol. Like triazolam, zolpidem decreases brain metabolism of glucose (Piercey et al. 1991).

The data concerning zolpidem’s ability to produce tolerance and physical dependence have shown conflicting results. In some animal models, zolpidem does not produce tolerance or physical dependence (Perrault et al. 1992). Mice were administered zolpidem or midazolam (both 30 mg/kg) by gastric intubation for 10 days. Those treated with midazolam, but not zolpidem, showed tolerance to the drug’s sedative effects and a lowered seizure threshold after the drug was stopped. Further, the benzodiazepine antagonist flumazenil precipitated withdrawal in the midazolam-treated animals but not in those treated with zolpidem.

Studies of baboons suggested that zolpidem is reinforcing and that it produces tolerance and physical dependence (Griffiths et al. 1992). In a free-choice paradigm, baboons consistently self-administered zolpidem intravenously at higher rates than either the vehicle solution alone or the triazolam. After 2 weeks of zolpidem self-administration, substitution of the vehicle solution alone resulted in suppression of food-pellet intake, which the investigators interpreted as zolpidem withdrawal. Baboons trained to discriminate oral doses of either phenobarbital (10 mg/kg) or lorazepam (1.8 mg/kg) from placebo responded to zolpidem as though it were an active drug more than 80% of the time. In another experiment, animals developed tolerance to zolpidem-induced ataxia and sedation during 7 days of drug administration. The investigators concluded that the rates of self-administration of zolpidem were similar to those of pentobarbital and higher than those maintained by 11 benzodiazepines that they had studied.

Case reports of psychosis have been described from therapeutic doses of zolpidem. A report from Belgium described two cases of transient psychosis after the first dose of 10 mg of zolpidem (Anseau et al. 1992). Neither patient had a history of drug abuse or misuse nor were they using alcohol. Both patients experienced a transient psychosis with visual hallucinations beginning 20–30 minutes after 10 mg of zolpidem. Both patients had previously used benzodiazepines without difficulty and both were amnestic for the psychotic episode.

A report from Spain described a 20-year-old woman with severe anorexia who became terrified by visual hallucinations and illusions 20 minutes after taking a 10-mg dose of zolpidem (Iruela et al. 1993). She had full recall of the psychotic episode. A week later she took a 5-mg dose of zolpidem and experienced a similar episode of reduced intensity. A week later, she took 2.5 mg and again experienced visual distortions. Additional case reports of psychosis have been reported in the US (Markowitz and Brewerton 1996, Pitter et al. 1997).

Zaleplon

Zaleplon (Sonata) is a pyrazolopyrimidine approved by the Food and Drug Administration (FDA) for marketing in the US in 1999. Like zolpidem it is chemically unrelated to the benzodiazepines, but binds on the same modulatory site on the GABA<sub>A</sub> receptor. Studies in baboons (Ator et al. 2000) and healthy volunteers with a history of drug abuse (Rush et al. 1999) suggest abuse potential similar to triazolam. Peak plasma concentration occurs about 1 hour following oral ingestion. It is rapidly metabolized with a half-life of about 1 hour. Impairment of short-term memory may occur at dosages of 10–20 mg.

Zopiclone

Zopiclone is a racemic mixture of cyclopyrrolone stereoisomers usually marketed in a 7.5 mg dose. The S-isomer is active at the GABA<sub>A</sub> receptor, and the R-isomer has no hypnotic effect (Carlson Haskew et al. 2001). Zopiclone is not marketed in the US, but is available in Canada and many other countries under trade name of Imovane or Zimovane in a 7.5 mg dose. Eszopiclone and zopiclone also have abuse potential similar to triazolam (Griffiths and Johnson 2005). The report of the International Narcotics Control Board 2006 noted that zopiclone was being diverted and abused in Argentina (INCB 2006). Short-term use has not shown evidence of dependence or physiological withdrawal (Wadworth and McCathie 1993). In a report of four case histories, zopiclone was reported to show tolerance and withdrawal (Jones and Sullivan 1998). (Hajak et al. 2003 provide a review of abuse and dependence and case reports. Withdrawal seizures were reported in a 36-year-old male taking 60–90 mg/day (Aranko et al. 1991) and in more recent case reports (Flynn and Cox 2006).
Acute Intoxication with Sedative–Hypnotics

The acute toxicity of sedative–hypnotics consists of slurred speech, incoordination, ataxia, sustained nystagmus, impaired judgment, and mood lability. When taken in large amounts sedative–hypnotics produce progressive respiratory depression and coma. The amount of respiratory depression produced by the benzodiazepines is much less than that produced by the barbiturates and other sedative–hypnotics. Consistent with its general approach, the DSM-IV-TR diagnosis of intoxication requires “clinically significant maladaptive behavioral or psychological changes” developing after drug use in addition to the signs and symptoms of acute toxicity. The DSM-IV-TR criteria for intoxication are shown above.

Dependence

Sedative–hypnotics can produce tolerance and physiological dependence. Physiological dependence can be induced within several days with continuous infusion of anesthetic doses. Patients who are taking barbiturates daily, for example, for a month or more above the upper therapeutic range listed in Table 64–1 should be presumed to be physically dependent and in need of medically managed detoxification.

Withdrawal Syndrome

The withdrawal syndrome arising from the discontinuation of short-acting sedative–hypnotics is similar to that from stopping or cutting down on the use of alcohol. Signs and symptoms of sedative–hypnotic withdrawal include anxiety, tremors, nightmares, insomnia, anorexia, nausea, vomiting, postural hypotension, seizures, delirium, and hyperpyrexia. The syndrome is qualitatively similar for all sedative–hypnotics; however, the time course of symptoms depends on the particular drug. With short-acting sedative–hypnotics (e.g., pentobarbital, secobarbital, meprobamate, oxazepam, alprazolam, and triazolam), withdrawal symptoms typically begin 12–24 hours after the last dose and peak in intensity between 24 and 72 hours (symptoms may develop more slowly in patients with liver disease or in the elderly because of decreased drug metabolism). With long-acting drugs (e.g., phenobarbital,
diazepam, and chlordiazepoxide), withdrawal signs and symptoms peak on the fifth to eighth day.

During untreated sedative–hypnotic withdrawal, the electroencephalogram (EEG) may show paroxysmal bursts of high-voltage, low-frequency activity that precedes the development of seizures. The withdrawal delirium may include confusion, visual and auditory hallucinations. The delirium generally follows a period of insomnia. Some patients may have only delirium; others only seizures; and some may have both delirium and convulsions.

As is described in the later section on benzodiazepines, benzodiazepines may also produce a severe, protracted withdrawal syndrome, and withdrawal symptoms may be produced in some patients after cessation of long-term therapeutic dosing.

Iatrogenic Dependence
Patients treated for months to years with benzodiazepines and other sedative–hypnotics may become physically dependent on sedative–hypnotics. The possibility of physical dependence should be discussed with the patient and, in some cases the patient’s family before initiating long-term treatment. Physical dependence as a process of neuroadaptation should be explained. Patients should be advised against abruptly stopping the medication, particularly if doses beyond the usual recommended doses are prescribed, because of the possibility of developing severe withdrawal symptoms, including withdrawal seizures.

Diagnosis and Differential Diagnosis
The diagnosis of sedative–hypnotic abuse and dependence is based primarily on drug-use history and the DSM-IV-TR criteria of behavior dysfunction caused by the drug. With dependence developing from prescribed use, the practical difficulty is determining when dysfunction is a result of the sedative–hypnotic use rather than the disorder for which the medication was prescribed. Clearly, intoxication on medications should be avoided; however, subtle memory dysfunction or emergence of symptoms (e.g., anxiety, insomnia) similar to those predating medication may be difficult to distinguish from rebound or withdrawal symptoms.

Psychiatric Comorbidity
Numerous studies document a high rate of psychopathological conditions among alcohol and drug abusers. Although abuse of drugs can induce psychopathology, particularly depression, it is often impossible while a patient is using drugs or even in early recovery to assess whether the drug use is driving the psychopathology or the psychopathology is driving the drug abuse. Clearly, some drug abusers have severe underlying psychopathological conditions that must be treated if patients are to remain abstinent and functional.

Patients with severe underlying psychiatric disorders may have unrealistic hopes of becoming medication-free. Often the origin of request for benzodiazepine withdrawal comes from concerned friends or relatives. Patients’ “problems” may be reframed as the use of “addictive medications” or “dependence” rather than the underlying psychopathology. As a practical matter, a trial of medication discontinuation may be undertaken with the understanding that return to a benzodiazepine or use of an antidepressant or other medications may be appropriate.

Withdrawal Syndrome
Physiological dependence on sedative–hypnotics may occur after long-term use of amounts greater than normally prescribed or recommended, or for some individuals, long-term use of therapeutic doses. The withdrawal syndrome manifests differently. With long-term therapeutic use, it is often difficult to differentiate a return of original symptoms (e.g., insomnia, panic attacks, generalized anxiety) from withdrawal signs and symptoms. For some patients, the symptoms of withdrawal continue months to years following discontinuation. Long-term symptoms following withdrawal that are attributed to withdrawal and not return of original symptoms is commonly characterized in the addiction medicine literature as a “protracted withdrawal syndrome.” The evidence for protracted withdrawal evolves primarily from clinical observation.

Internet sites provide patients information and provide a forum where patients can exchange information about their experiences with dependence on benzodiazepine and the Z-drugs. TRAP, an acronym for the Tranquilliser Recover and Awareness Place, hosts several, Web sites5 for people who are having difficulty discontinuing their drug use. Another organization, The Council for Information on Tranquillisers and Antidepressants (CITA) has a Web site offering support and information for people who have become “involuntarily addicted to their prescribed tranquillisers.” The premise of these sites is that most doctors are not aware of the addictive potential of benzodiazepines when prescribed for more than a few weeks and that they don’t know that behavioral dysfunction and signs and symptoms that arise during medication discontinuation are actually protracted withdrawal symptoms. In this context, the terms “addiction” and “severe symptoms on discontinuation” are synonymous.

High-Dose Withdrawal Syndrome
Studies of humans have established that large doses of chlordiazepoxide (Hollister et al. 1961) and diazepam (Hollister et al. 1963) taken for one month or more produce a withdrawal syndrome that is clinically similar to the withdrawal syndrome produced by high doses of barbiturates that had been previously described (Isbell 1950). Other benzodiazepines have not been studied under such precise conditions, but numerous case reports leave no doubt that they also produce a similar withdrawal syndrome when taken in excess of the upper therapeutic range.

Withdrawal symptoms can be systematically monitored with the Benzodiazepine Withdrawal Symptom Questionnaire (BWSQ). Initially developed from clinical observations (Tyrer et al. 1990), its test-retest reliability, construct validity, and predictive validity have been demonstrated (Couvée and Zitman 2002). Low scores during the last phases of

tapering off predicted limited or no use of benzodiazepines during the year following discontinuation.

**Low-Dose Withdrawal Syndrome**

Many people who have taken benzodiazepines in therapeutic doses for months to years can abruptly discontinue the drug without developing withdrawal symptoms. Others develop symptoms ranging from mild to severe when the benzodiazepine is discontinued. Characteristically, patients tolerate a gradual tapering of the benzodiazepine until they are at 10–20% of their peak dose. Further reductions in benzodiazepine dose then cause patients to become increasingly symptomatic. In addiction medicine literature, the low-dose withdrawal may be called therapeutic-dose withdrawal, normal-dose withdrawal, or benzodiazepine discontinuation syndrome. The symptoms can ultimately be categorized as symptom reemergence, symptom rebound, or a prolonged withdrawal syndrome.

Many patients experience a transient increase in symptoms for 1–2 weeks after benzodiazepine withdrawal. The symptoms are an intensified return of the symptoms for which the benzodiazepine was prescribed. This transient form of symptoms intensification is called symptom rebound. The term comes from sleep research in which rebound insomnia is commonly observed after sedative-hypnotic use. Symptom rebound lasts a few days to weeks after discontinuation (American Psychiatric Association Task Force on Benzodiazepine Dependency 1990). Symptom rebound is the most common withdrawal consequence of prolonged benzodiazepine use.

Following discontinuation the symptoms for which the sedative-hypnotic has been taken may return. This is referred to as symptom reemergence (or recrudescence). In other words, the patient's symptoms, such as anxiety, insomnia, or muscle tension, which had abated during benzodiazepine treatment return.

The reason for making a distinction between symptom rebound and symptom reemergence is that symptom reemergence suggests that the original symptoms are still present and must be treated. Symptom rebound is a transient withdrawal syndrome that will subside over time.

A few patients experience a severe, protracted withdrawal syndrome that includes symptoms (e.g., paresthesia and psychosis) that were not present before.

**Protracted Withdrawal Syndrome**

Protracted benzodiazepine withdrawal may consist of relatively mild withdrawal symptoms such as anxiety, mood instability, and sleep disturbance similar to the protracted withdrawal syndrome described for alcohol and other drugs. In some patients, the protracted withdrawal syndrome from benzodiazepines can be severe and disabling and last many months.

There is considerable controversy surrounding even the existence of this syndrome, which evolves primarily from the addiction medicine literature. Many symptoms are nonspecific and often mimic an obsessive-compulsive disorder (OCD) with psychotic features. As a practical matter, it is often difficult in the clinical setting to separate symptom reemergence from protracted withdrawal. New symptoms, such as increased sensitivity to sound, light, and touch and paresthesia, are particularly suggestive of low-dose withdrawal.

The protracted benzodiazepine withdrawal has no pathognomonic signs or symptoms, and the broad range of nonspecific symptoms produced by the protracted benzodiazepine withdrawal syndrome could also be the result of agitated depression, GAD, panic disorder, partial complex seizures, and schizophrenia. The time course of symptom resolution is the primary differentiating feature between symptoms generated by withdrawal and symptom reemergence. Symptoms from withdrawal gradually subside with continued abstinence, whereas symptom reemergence and symptom sensitization do not.

The waxing and waning of symptom intensity are characteristic of the low-dose protracted benzodiazepine withdrawal syndrome. Patients are sometimes asymptomatic for several days, and then, without apparent reason they become acutely anxious. Often there are concomitant physiological signs (e.g., dilated pupils, increased resting heart rate, and increased blood pressure). The intense waxing and waning of symptoms are important in distinguishing low-dose withdrawal symptoms from symptom reemergence.

**Risk Factors for Low-Dose Withdrawal**

Some drugs or medications may facilitate neuroadaptation by increasing the affinity of benzodiazepines for their receptors. Phenobarbital, for example, increases the affinity of diazepam to benzodiazepine receptors (Skolnick et al. 1981, Olsen and Loeb-Lundberg 1981) and prior treatment with phenobarbital increases the intensity of chlordiazepoxide (45 mg/day) withdrawal symptoms (Covi et al. 1973). A genetic component is likely. Patients at increased risk for development of the low-dose withdrawal syndrome are those with a family or personal history of alcoholism, those who use alcohol daily, and those who concomitantly use other sedatives. Case-control studies suggest that patients with a history of addiction, particularly to other sedative-hypnotics, are at high risk for low-dose benzodiazepine dependence. The short-acting, high-milligram-potency benzodiazepines appear to produce a more intense low-dose withdrawal syndrome (Rickels et al. 1990).

**Physical Dependence in Nondrug-Dependent Medical Patients**

Long-term use of benzodiazepines can result in physical dependence in nondrug-dependent medical patients. Withdrawal symptoms “or” return of symptoms suppressed by the benzodiazepines may make discontinuation difficult.

Some patients who are physically dependent on or unable to discontinue a medication do not necessarily have a substance-use disorder. Physical dependence results from neuroadaptive changes resulting from long-term exposure to a medication. Inability to discontinue the medication may simply mean that patients are unwilling to tolerate the severity of postwithdrawal symptoms that develop. In the absence of medication-produced dysfunction, the continuation of the medication may be an appropriate choice. Patients who do not have a substance-use disorder take medications in the quantity prescribed. They follow
their physicians’ recommendations, and they do not mix them with drugs of abuse.

Presentation in Drug-Abusing Patients
Abusers of alcohol and other drugs rarely present for primary treatment of sedative–hypnotic dependency. From the drug-abusing patient’s point of view, sedative–hypnotic use is an effort to self-medicate anxiety or insomnia, which is often the result of alcohol or stimulant abuse. Despite their assertion that the medication is being taken for symptom relief, they often take the medication in larger than physician-prescribed doses, combine the medication with intoxicating amounts of alcohol or other drugs, and purchase medications from street sources. They may also use the sedative–hypnotic as an intoxicant when other drugs are not available.

Cultural and Minority Issues in Assessment and Treatment
There are marked class and ethnic differences in beliefs and values about the use of intoxicants and medications. The dominant culture in the US prohibits the use of any intoxicant other than alcohol and places limits on tolerated behaviors while intoxicated (e.g., public intoxication, driving an automobile while intoxicated).

Many patients view the distinction between medication and recreational drugs as arbitrary and pharmacologically irrational. For some, medications such as methaqualone simply extend the number of available intoxicants. A strength of the drug abuse and dependence criteria of DSM-IV-TR is that the diagnostic criteria for abuse and dependence are dysfunctional behaviors that most people would agree are pathological.

Evaluation and Diagnosis
Drug Use History
The patient’s drug use history is usually the first source of information that is used in assessing sedative–hypnotic abuse or dependence. If the sedative–hypnotics were being used for treatment of insomnia or anxiety, the history is often best obtained as part of the history of the primary disorder and its response to treatment. A detailed history of use of all sedative–hypnotics, including alcohol, should be elicited from the patient. When framed in terms of the presenting disorder, patients are generally more candid about their drug use and their relationships with past treatment physicians.

For many reasons, patients may minimize or exaggerate their drug use and not accurately report the behavioral consequences of their use. High doses of benzodiazepines or therapeutic doses of benzodiazepines in combination with alcohol may disrupt memory. Patients are likely to attribute impairment of function to the underlying disorder rather than to the medication use. Observations of patients’ behavior by family members can be a source of valuable information. Whenever possible, the patient’s history should be supplemented by medical and pharmacy records to help piece together as accurate a picture of drug use as possible. Pharmacy records may be helpful in establishing and verifying patient’s drug use history, and urine testing can be useful in verifying recent drug use history.

Patients who are obtaining some or all of their medication from street sources may not know what they have been taking, as deception in the street-drug marketplace is common. For example, tablets sold as methaqualone have been found to contain phenobarbital or diazepam.

Drug Abusers
Many abusers of alcohol or other drugs have symptoms that would reasonably indicate treatment with benzodiazepines or other sedatives if they were not drug abusers. Treating drug abusers with benzodiazepines or other sedatives, while they are still abusing drugs, is generally not helpful however. Such patients are at high risk of misusing or abusing the medications, and the medication may enable them to continue abuse of their primary drug. Drug abusers who are symptomatic because of drug toxicity need hospitalization and detoxification. In patients with drug dependence disorders, abstinence from all abusable medications is the preferred treatment goal, particularly during the first 6 months of abstinence. In patients who do not have a drug dependence disorder, return to benzodiazepine use after detoxification may have a different implication than among patients with a drug dependence disorder. The term relapse, which is clearly pejorative, could reasonably be applied to patients who self-administer a benzodiazepine when benzodiazepine abstinence is the agreed on goal of treatment. However, the term relapse should not be applied to patients without a substance abuse disorder who return to prescribed benzodiazepine use because emerging symptoms are not otherwise manageable.

Most patients who are being prescribed long-term benzodiazepine therapy have underlying major depressive disorder, panic disorder, or GAD. The clinical dilemma is deciding which patients are receiving appropriate maintenance therapy for a chronic psychiatric condition. Physical dependence on benzodiazepines may be acceptable if the patient’s psychosocial function and disabling anxiety symptoms are ameliorated. The reason for the patient’s request for benzodiazepine withdrawal from long-term, stable dosing should be carefully explored. Valid reasons to discontinue benzodiazepine treatment include: (1) breakthrough of symptoms that were previously well controlled; (2) impairment of memory or other neurocognitive function; and (3) abuse of alcohol, cocaine, or other medications.

Physical Findings
Intoxication on sedative–hypnotics may produce slurred speech, unsteady gait, and sustained horizontal nystagmus. Sustained horizontal nystagmus is a reliable indicator of sedative–hypnotic intoxication. Onset of tremor, abnormal sweating, and blood pressure or pulse increase may be produced by sedative–hypnotic withdrawal.

Laboratory Tests
Urine toxicology can be useful in monitoring patients’ use of drugs and in confirming a history of drug or medication use. The detection time varies widely for benzodiazepines. Diazepam or chlordiazepoxide may be detected for weeks following chronic or high-dose use, whereas others, such as alprazolam or clonazepam, may not be detectable in routine toxicity urinalysis. Because of the variability in
laboratory cut-offs and detection time and different drugs included in the screening panel, the analytical laboratory should be asked about what they routinely screen for and the detection limits.

Definitive diagnosis of a psychiatric disorder during early abstinence is often not possible because protracted withdrawal symptoms may mimic anxiety disorders. Disruption of sleep architecture for days to months after drug withdrawal may occur. If the sedative–hypnotic dependence has developed secondary to stimulant or alcohol use, primary treatment of the chemical dependence should occur first. Often the symptoms that were driving the sedative–hypnotic use disappear after the patient is drug abstinent.

**Treatment**

Once a diagnosis of sedative–hypnotic dependence is manifested it is unlikely that a patient will be able to return to controlled, therapeutic use of sedative–hypnotics. All sedative–hypnotics, including alcohol, are cross-tolerant, and physical dependence and tolerance are quickly reestablished if a patient resumes use of sedative–hypnotics.

If after sedative–hypnotic withdrawal the patient has another primarily psychiatric disorder, such as generalized anxiety disorder (GAD), panic attacks, or insomnia, alternate treatment strategies other than sedative–hypnotics should be used if possible.

Treatment of sedative–hypnotic dependence that has developed as a result of treatment of an underlying psychiatric disorder is usually a lengthy undertaking. The goals of the first phase of treatment are to establish the diagnosis and, to the extent possible, delineate the comorbid psychiatric diagnoses and establish a therapeutic relationship with the patient. The art of treatment is knowing when the therapeutic alliance is sufficiently established to institute drug withdrawal, and knowing when outpatient treatment is not progressing adequately.

In the era of managed health care, it can be difficult, if not impossible, to get medical payors to authorize inpatient treatment of “low-dose” dependence. Although patients may experience intensely disturbing symptoms and may not be able to tolerate symptoms and comply with medication regimens, medical reviewers may deny hospitalization for treatment of dependence, and attribute symptoms arising during withdrawal as mismanagement of symptom reemergence.

**High-Dose Withdrawal**

For discontinuation of benzodiazepines or nonbenzodiazepine hypnotics that are being used at dosages above those generally prescribed, one pharmacotherapy strategy is to substitute phenobarbital and stabilization period of 3–7 days, to taper the phenobarbital 30 mg/day. The phenobarbital withdrawal conversion equivalents are shown in Table 64–3. The dose conversions computed using Table 64–3 prevent the emergence of severe withdrawal of the classic sedative–hypnotic type. As discussed next, some patients who take high doses of benzodiazepines, or even therapeutic doses for months to years, may have prolonged withdrawal symptoms.

Three general strategies are used for withdrawing patients from sedative–hypnotics, including benzodiazepines. The first is to use decreasing doses of the agent of dependence. The second is to substitute phenobarbital or some other long-acting barbiturate for the addicting agent, and gradually withdraw the substitute medication (Smith and Wesson 1970, 1971). The third, used for patients with a dependence on both alcohol and a benzodiazepine, is to substitute a long-acting benzodiazepine, such as chlor Diazepoxide, and taper it during 1–2 weeks.

Phenobarbital substitution has practical and pharmacological advantages for some patients. Phenobarbital is readily available and inexpensive. It is long acting and consequently there is little fluctuations in blood level between doses. During benzodiazepine withdrawal, the GABA A receptor may undergo changes that render an individual less sensitive to benzodiazepine agonists. Phenobarbital may owe its utility in benzodiazepine tolerant patients because barbiturates remain effective on benzodiazepine insensitive GABA A receptors (Akk 2004). Lethal doses of phenobarbital are many times higher than toxic doses, and the signs of toxicity (e.g., sustained nystagmus, slurred speech, and ataxia) are easy to observe. Finally, phenobarbital intoxication does not produce euphoria or behavioral disinhibition, so patients are more likely to view it as a medication.

The preferred withdrawal strategy depends on the particular benzodiazepine, the involvement of other drugs of dependence, and the clinical setting in which the detoxification program takes place. The gradual reduction of the benzodiazepine of dependence is used primarily in medical settings for dependence arising from treatment of an underlying condition. The patient must be cooperative, must be able to adhere to dosing regimens, and must not be abusing alcohol or other drugs.

Substitution of phenobarbital can also be used to withdraw patients who have lost control of their benzodiazepine use or who are polydrug dependent. Phenobarbital substitution has the broadest use for all sedative–hypnotic drug dependencies and is widely used in drug treatment programs. There has been growing support from the treatment community for the use of newer anticonvulsant medications such as gabapentin, oxcarbazepine, and tiagabine for management of substance abuse and abuse-related sleep disorders, as well as for relapse prevention, but their utility as a broad withdrawal substitution has not been demonstrated (Gentry et al. 2002).

**Stabilization Phase**

The patient’s history of drug use during the month before treatment is used to compute the stabilization dose of phenobarbital. Although many addicts exaggerate the number of pills they are taking, the patient’s history is the best guide to initiating pharmacotherapy for withdrawal. Patients who have overstated the amount of drug that they have taken will become intoxicated during the first day or two of treatment. Intoxication is easily managed by omitting one or more doses of phenobarbital and reducing the daily dose.

To compute the initial daily starting dose of phenobarbital, the patient’s average daily use of each sedative–hypnotic is estimated. Next, the patient’s average daily sedative–hypnotic dose for each drug is converted to its phenobarbital withdrawal equivalent by multiplying the average...
Before receiving each dose of phenobarbital, the patient is checked for signs of phenobarbital toxicity: sustained nystagmus, slurred speech, or ataxia. Of these, sustained nystagmus is the most reliable. If nystagmus is present, the scheduled dose of phenobarbital is withheld. If all three signs are present the next two doses of phenobarbital are withheld, and the daily dosage of phenobarbital for the next day is halved.

If the patient is in acute withdrawal and has had or is in danger of having withdrawal seizures, the initial dose of phenobarbital is administered by intramuscular injection. If sustained horizontal nystagmus or other signs of intoxication develop after 1–2 hours after the intramuscular dose, the patient is in no immediate danger from barbiturate withdrawal. Patients are maintained with the initial dosing schedule of phenobarbital for 2 days. If the patient has neither signs of withdrawal nor phenobarbital toxicity (slurred speech, nystagmus, unsteady gait) phenobarbital withdrawal is begun.

**Withdrawal Phase**

Unless the patient develops signs and symptoms of phenobarbital toxicity or sedative–hypnotic withdrawal, phenobarbital is decreased by 30 mg/day. Should signs of phenobarbital toxicity develop during withdrawal, the daily phenobarbital dose is decreased by 50% and the 30 mg/day withdrawal is continued from the reduced phenobarbital dose. Should the patient have objective signs of sedative–hypnotic withdrawal, the daily dose is increased by 50% and the patient is restabilized before continuing the withdrawal.

**Protracted Benzodiazepine Withdrawal**

Phenobarbital conversions based on Table 64–3 are not adequate to suppress symptoms. For example, someone discontinuing 20 mg of diazepam would have a computed phenobarbital conversion of 60 mg. In managing low-dose withdrawal, an approach is to begin with about 200 mg/day of phenobarbital and then taper the phenobarbital, slowly as tolerated. If palpitations or other symptoms of autonomic hyperactivity are bothersome, beta-adrenergic blockers, such as propranolol or 2-adrenergic agonists, such as clonidine, may be useful adjuncts. Reports on the use of clonidine to reduce benzodiazepine withdrawal severity have yielded mixed results.

**Emerging Alternative Pharmacotherapy for Treatment of Benzodiazepine Dependence**

Several small studies have explored the use of the benzodiazepine antagonist, flumazenil, for managing symptoms that emerged after benzodiazepine discontinuation. In an early, open-label pilot study, Lader and Morton (1992) used a single flumazenil injection administered by slow intravenous infusion of dosages between 0.2 and 2.0 mg) in 11 patients to assess the effect on persistent symptoms following withdrawal. Because of concern about precipitating benzodiazepine withdrawal, all patients had been off benzodiazepines from between 1 month to 5 years before flumazenil treatment. In an effort to assess placebo effects,
a saline infusion preceded the first flumazenil infusion. They reported that symptoms were ameliorated for hours to days following flumazenil and suggested flumazenil as a potential treatment for the symptoms occurring after benzodiazepine discontinuation (Saxon et al. 1997, Gerra et al. 2002).

Current package inserts for flumazenil (generic and Roche) caution that insufficient data exist to support the use of flumazenil for treatment of benzodiazepine dependence.

**Low-Dose Withdrawal**

Discontinuation of sedative hypnotics can present challenges to the patient and the physician. As previously discussed, determining whether symptoms that occur are the result of symptom reemergence, rebound, or physiological withdrawal can often not be objectively established with certainty. New symptoms such as paresthesias and unusual sensitivity to light or sound suggest a withdrawal syndrome whereas emergence of symptoms similar to those that the patient was having before sedative-hypnotic therapy suggests symptom reemergence.

The phenobarbital withdrawal equivalences that would be computed from Tables 64–2 and 64–3 will not be sufficient to manage low-dose withdrawal. For benzodiazepine withdrawal or the nonbenzodiazepine hypnotics, gabapentin 1200–2000 mg per day may provide symptom control. If phenobarbital is used, initial dosages of 200 mg/day may be required.

**Psychosocial Treatment**

Psychosocial treatments are those services in addition to the medical management of withdrawal. When provided by psychiatrists, psychotherapy may be combined with medical management. Usually, in an inpatient drug abuse treatment setting, psychosocial services are groups and counseling provided by chemical dependence counselors, who may be in recovery from drug or alcohol dependence. While there are specific types of therapy, such as relapse prevention, motivational enhancement or cognitive behavioral therapy, most counselors use a blend of their own recovery experience, the aphorisms of 12-step recovery, and professional training.

**Psychotherapy**

Insight-oriented psychotherapy and specifically psychoanalysis are much maligned as treatment of drug dependence. Two reasons deserve serious consideration: some psychotherapists approach treatment of drug dependence as though the drug use is a secondary symptom of neurosis that will cease if the underlying causes are understood. Additionally, insight-oriented psychotherapy itself may mobilize strong affect, memories, or emotions that patients in early or a fragile recovery are unable to tolerate, which may drive relapse to drug abuse.

The problem with drug dependence as a symptom of a neurosis model is that once drug abuse or dependence becomes established the drug use takes on a life of its own regardless of the underlying reason for initiation. Insight-oriented psychotherapy is rarely successful in stopping the drug use. During early recovery, most patients are coping with protracted withdrawal symptoms, repairing relationships, and learning to function without reliance on psychoactive drugs. Patients with underlying psychiatric disorders may have the additional burden of emergence of symptoms that had been ameliorated by their drug use. Psychotherapy during early recovery should be supportive and cognitive–behavioral and focused on coping with current life difficulties. Psychotherapists should remain vigilant for symptoms of panic attacks, generalized anxiety, depression, or sleep disturbances that interfere with function and be prepared to initiate appropriate psychopharmacological or somatic treatments when appropriate.

Psychotherapy can, however, have an important role in motivating a patient for primary treatment of drug dependence. Therapists can help break down patients’ denial of their drug dependence by helping them see how drug use is interfering with relationships and undermining their ability to achieve their goals. In some instances, it is desirable to continue the psychotherapeutic relationship while the patient is undergoing treatment for chemical dependence. With some drug abusers, it is desirable to separate the medication management from psychotherapy to prevent the psychotherapy from becoming bogged down in discussions of medications and medication side effects.

**Twelve-Step Recovery**

Alcoholics Anonymous, Narcotics Anonymous, and Cocaine Anonymous groups are important treatment adjuncts for many people recovering from alcohol and other forms of drug dependence. Although many groups are becoming more tolerant of appropriate use of pharmacotherapies, many individuals who attend 12-step recovery meetings are adamantly opposed to any form of psychotropic medication use and may counsel fellow members to stop their use. Strong opposition to medications is usually based on their own or friends’ bad experience with medications. Some individuals recover without medications and believe that recovery is of better quality if not achieved with a pharmacological crutch.

Patients with underlying psychiatric disorders and the need for treatment with psychopharmacotherapeutic medications often require ongoing support from their psychotherapist if they must have medication.

**Clinical Vignette 1**

A 33-year-old woman was referred by her internist for treatment of alcohol dependence after an overdose of alprazolam (Xanax) and alcohol. The patient had ingested about 30 tablets of alprazolam (2 mg) and a bottle of wine after an argument with her husband. The patient and her husband were in the process of an acrimonious separation, and during the 3 months before her hospitalization, the patient had increased her alcohol consumption from one or two glasses of wine with the evening meal to 1.5 bottles of wine each night. The patient stated that she had wanted to die and that she had heard that the combination of alprazolam and alcohol was lethal. She had not previously made a suicide attempt; however, she was under the ongoing care of a psychiatrist because of panic attacks. A previous psychiatrist had started the patient with alprazolam about...
Clinical Vignette 1 continued

6 years before the overdose. Before treatment with alprazolam, her panic attacks had become disabling. While she was taking 4 mg/day of alprazolam, the panic attacks became infrequent, and much attenuated in intensity. She had resumed employment as a travel agent. As her alcohol use increased, the frequency and intensity of her panic attacks increased. Until the overdose, she took alprazolam exactly as prescribed, 2 mg twice a day at the same time each day. Her psychiatrist verified that her refills were consistent with her history. The patient was frightened by having overdosed and acknowledged that her alcohol use was excessive and that she needed treatment; however, she did not want to discontinue alprazolam because she feared worsening of the panic attacks.

Discussion

This patient presents a challenging clinical situation, often referred to in the chemical dependence treatment field as dual diagnosis: a major psychiatric disorder and chemical dependence. Alcohol and drug treatment programs generally want patients to discontinue all mood-altering medications, particularly those with abuse potential, when they enter treatment. Chemical dependence treatment staffs often observe that alcohol-abusing patients increase their use of prescription medication when they stop drinking.

Because the patient’s panic attacks had been disabling, and because the alcohol abuse seemed a response to an acute situational stress, the patient began outpatient (4 nights/week) chemical dependence treatment, she and her husband began couples therapy, and the patient increased the frequency of visits with her psychiatrist. With the increased support, the patient completed the separation from her husband, remained abstinent from alcohol, and remained on a carefully monitored dose of alprazolam.

Clinical Vignette 2

A 45-year-old man entered inpatient treatment for alcohol dependence. He lived alone and acknowledged drinking up to a fifth of vodka per day. He made many attempts to stop drinking; however, each time, within 24 hours, he became tremulous, sweaty, and nauseous. During the past 10 years, he had had three inpatient detoxifications from alcohol, each followed by a year or more of abstinence. After treatment, he attended three to five Alcoholics Anonymous meetings per week. When asked about medication use, he said that he had been taking lorazepam (Ativan), but it did not help so he stopped it. He denied use of other medications. He denied ever having had a withdrawal seizure.

After admission to the hospital, the patient was treated with chlordiazepoxide (Librium), 25–50 mg every hour as needed, for alcohol withdrawal signs and symptoms. For the first 24 hours, he received 250 mg of chlordiazepoxide. He appeared comfortable and, on the second hospital day, participated in group therapy. While sitting in group therapy, he suddenly stood up, fell forward, and had a grand mal seizure lasting about 2 minutes. Subsequently, he revealed that he had been taking 6–12 mg/day of lorazepam up to the day before admission.

Discussion

For many reasons, patients may not reveal all their use of prescription medications or street drugs when they enter an alcohol or drug abuse treatment program. In some instances, patients may want to “protect” the prescribing physician or keep access to medications that would not be sanctioned by physicians working in an alcohol or drug treatment program. The psychotropic medication history is often best obtained as part of the general medical history, in which the patient is asked about any recent treatment of medical problems. Patients are often put at ease by overt assurances of confidentiality and by an explanation of why the drug use history is needed. Indirect questions may be productive—for example, “If we had tested your urine yesterday for all drugs and medications that you had taken during the 3 days just before you came in, what would the tests have shown?” This kind of questioning often provokes patients to ask about if, or how long, a particular drug or medication they are taking can be detected.

Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria

The DSM-IV-TR and International Classification of Diseases, 10th Revision (ICD-10) Criteria sets for Sedative, Hypnotic, or Anxiolytic Intoxication are almost equivalent (except that ICD-10 also includes “erythematous skin lesions or blisters.” The 11 and ICD-10 symptom lists for Sedative, Hypnotic, or Anxiolytic Withdrawal include some different items: the ICD-10 list has craving, postural hypotension, headache, malaise or weakness, and paranoid ideation and do not include the DSM-IV-TR anxiety item.

Acknowledgment

The authors would like to acknowledge the role of Dr. Ezra Holston in his assistance in the literature review and in critically reviewing successive drafts of the manuscript.

“Like a stone thrown onto the smooth surface of a peaceful pond, schizophrenia disrupts lives in ever-expanding concentric circles, so that many lives and many people suffer the pain that arises from a single case.”

Nancy Andreason, MD, Ph.D.

Historical Overview
In prehistoric times, aberrant behavior was ascribed to magic and religious notions of evil forces that invaded and inhabited a human body. Many cultures treated deviant behavior with the practice of trephination, one of the earliest surgical procedures known (Figure 65–1). Trephining was performed by boring a hole into the skull of a living person to free the evil spirits. Trephined skulls have been found in Peruvian ruins and in parts of Africa, where the procedure may still be performed. In primitive cultures, shamans, who were seen as healers and spiritual leaders, sought to extricate the negative powers from the body with medicinal herbs or ritual chanting and dancing. Interestingly, those who were considered shamans or spiritual healers were often mentally ill themselves. Later, hallucinations and delusions were attributed to the work of the devil or witchcraft. Those found guilty of such sins could be burned at the stake, leading to the unfortunate death of many people who most likely were suffering from severe mental illnesses.

Despite these prevailing religious and spiritual views of mental illness, scientific theory, and medical hypotheses were also considered. In ancient Greece, Hippocrates explained aberrant behavior and madness by relating it to internal imbalances of the four body humors. He stated that our emotions, both joyous and sorrowful, come from the brain. He went further to posit that when a brain is diseased, madness may ensue. Galen, a prominent physician in the 1st century AD, also attributed mental illness to the disturbances of the humors, a theory he had derived from Hippocrates. He expanded on the Hippocratic and Aristotelian notion of mania and melancholia and described abnormalities in emotion and thought as a result of spirits and temperature alterations in the brain. Furthermore, he believed mental illnesses could be broken down into subtypes including aspects of paranoia and despair.

In the 18th century, Philippe Pinel, a prominent French physician, was one in a growing list of predecessors who believed that mental illness was a disease of the central nervous system and one that could be caused by hereditary or environmental factors. In his work with the mentally ill, he was known for his compassionate treatment of patients.
believed that patients would benefit from being properly clothed and nourished and that, except in the most extreme circumstances, their chains should be removed, allowing them freedom within the hospital grounds. He offered instruction in how to handle patients who were potentially violent, with humane techniques that are used to this day. Pinel ended the common practice of viewing patients publicly for entertainment purposes. He implemented these humane changes in two French hospitals, Bicêtre and the Salpêtrière. Pinel was one of the early nosologists who categorized mental illness into subgroups and identified patients who had disturbances of intellect, emotion, or will. He also divided patients into those who had continuous symptoms and those who had signs of “intermittent madness” (Weiner 1992). These early concepts paved the way to our 21st century conceptualization of schizophrenia.

Modern Concept of Schizophrenia

Our modern understanding of schizophrenia can begin with a look back to the 19th century. Although there were several influential contributors to early psychiatric nosology, there are a few leaders in psychiatry who are thought to have laid the foundation for current diagnostic criteria. To understand how the most recent diagnostic guidelines have been developed, one must place them in their historical context.

Emil Kraepelin (1856–1926) was a German psychiatrist who devoted his life’s work to the task of describing and characterizing the symptoms his patients manifested. From these observations, he concluded that not all mental patients suffered from the same disease. He was one of the first to distinguish manic-depressive psychoses from other chronic psychotic illnesses (Kraepelin and Barclay 1919). Among the great contributions to the field of psychiatry are his insightful descriptions of the clinical presentation and course of these illnesses. In naming the chronic illness he saw, Kraepelin borrowed from the French psychiatrist Benedict Augustin Morel, who in the 1850s had used the term démence précoce to describe a previously normal young boy who suddenly manifested symptoms of mental deterioration. Kraepelin, with a slightly different conception of the symptom presentation, used the Latin of Morel’s term to label the more chronic illness “dementia praecox.” In contrast to Morel, Kraepelin emphasized the outcome of the illness in his descriptions. He believed that dementia praecox was characterized by early onset of symptoms followed by a progressive course culminating in dementia. Later he came to believe that not all patients with dementia praecox ended up in a demented state and a few even recovered. Kraepelin observed, however, that a common theme for these patients was that they experienced a withdrawn state with concomitant hallucinations or bizarre delusions with no impairment of consciousness, sensorium, or memory.

For Kraepelin, the description of the symptoms was of paramount importance, and he published a detailed account of his patients’ symptoms in a monograph entitled Demencia Praecox and Paraphrenia. He divided patients into three subtypes—hebephrenic, catatonic, and paranoid—and later described paraphrenia as being a separate clinical entity resembling paranoia with either systematized or nonsystematized beliefs and not characterized by the deterioration of personality as in dementia praecox.

Eugen Bleuler (1857–1939) was a Swiss psychiatrist who is known, among other things, for coining the term schizophrenia. Although erroneously defined at times as multiple personality disorder, this term means literally “splitting of the mind.” Bleuler used the word to capture his belief that this mental illness was one in which different aspects of the psyche were split, which resulted in the classical symptoms he went on to describe. In his paper entitled “Dementia praecox and the group of schizophrenias,” he put forth his theory that schizophrenia consisted of not just one illness with one etiological basis but a heterogeneous group of illnesses with distinguishing characteristics and clinical courses (Bleuler and Zinkin 1950). He differed from Kraepelin in believing that these illnesses were not as often characterized by an early onset and a terminal dementia. Bleuler expanded and modified earlier Kraepelinian concepts including the subdivisions of diagnoses and included the category of simple schizophrenia, which was eventually also adopted by Kraepelin.

Perhaps one of his most important contributions was Bleuler’s emphasis on the content of symptom presentation. To Bleuler all patients had at least one fundamental or primary symptom, but other accessory or secondary symptoms were also manifested clinically. Bleuler’s “four As,” as they are now commonly called, consisted of primary symptoms: profound ambivalence, a looseness of associations, disturbance of affect (either excitement or withdrawal), and autism, which he described as living in an internal, unrealistic world, separated from normal social interaction. Bleuler attempted to describe negativism, which he thought was not only a result of motor disturbance but also had psychic meaning, which he thought was important to understand. Although his symptom descriptions are not used in their entirety in modern diagnostic classification systems because of their limited specificity, the remnants of these descriptions can be seen in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV-TR) (American Psychiatric Association 2000).

Kurt Schneider (1887–1967) has probably contributed to our current diagnostic classifications more than any other person. Schneider studied both Kraepelin’s and Bleuler’s ideas during his psychiatric training in Germany (Hoenig...
From his reading and his own clinical experience, he formulated a list of symptoms that he believed could be identified in his schizophrenia patients.

Without positing etiological theories, Schneider described symptoms of first and second rank, based on which were most likely to be found in a patient with schizophrenia. According to Schneider, the diagnosis of schizophrenia was appropriate if the patient experienced just one first-rank symptom; the second-rank symptoms, although common in schizophrenia, were not as specific. His first-rank symptoms included delusions of thoughts being broadcast; feelings of an external force inserting thoughts or withdrawing them from the mind; thought interference; and the sensation of forces influencing behavior, will, or body functions. The first-rank symptoms also include specific hallucinatory experiences, such as hearing voices, often two or more, commenting on the patient’s behavior or criticizing the patient. The second-rank symptoms included paranoia, affective extremes, apathy or absence of emotions, and any hallucinatory experience other than those already described. Schneider’s description of these symptoms paved the way to modern diagnostic criteria used today.

**Diagnosis**

**Evolution of Structured Diagnostic Criteria for Schizophrenia**

A specific “operationalized” set of diagnostic criteria for schizophrenia was first brought to light in a paper published by Feighner and colleagues (1972) of the St. Louis group. They presented a list of symptoms and signs that provided a reliable system for differentiating diagnostic groups. The St. Louis group emphasized the pattern and the duration of symptoms (requiring 6 months of symptoms to reach a diagnosis of schizophrenia) without regard to the etiology of the illness being observed. Feighner’s group proposed that a set of consistent diagnostic criteria would facilitate and improve on research and clinical treatment of patients.

The research diagnostic criteria (RDC) were developed to improve diagnostic reliability in research, borrowing many of the concepts from the Feighner criteria and Schneiderian tradition. Unlike the Feighner criteria, the RDC diagnosis of schizophrenia does not require 6 months of active symptoms. Instead, schizophrenia is divided into three groups, based on temporal distinctions: acute (lasting 2 weeks to 6 months); intermediate, that is, subacute or subchronic (lasting 6 months to 2 years); and chronic (illness present for at least 2 years). This set of criteria excludes patients with a clear mood syndrome and assigns them to either an affective disorder or a schizoaffective disorder. For a diagnosis of schizophrenia, patients must have experienced two of nine symptoms listed, including delusions, thought disorder, hallucinations, or catatonic behavior. Many of these symptoms are derived directly from Schneiderian concepts. Diagnoses are assigned a degree of certainty (probable or definite) and are considered primary or secondary, based on the chronological presentation of concomitant illnesses. The RDC have remained essentially unchanged as other diagnostic classification systems have been modified and revised, which allows homogeneously defined groups of patients to be compared over time.

Structured diagnostic aids made up of standardized questions were developed to increase the reliability of diagnostic assessments. Wing’s present state examination (PSE) is an example. Like Schneider’s description of first- and second-rank symptoms, it consists of a checklist of experiences covering a period of 1 month before the interview. This particular symptom algorithm has been widely used and validated around the world since its invention in 1970. The PSE was influential in the development of the RDCs, and, moreover, the structured interview that can be used with the RDCs, the schedule for affective disorders and schizophrenia (SADS). Specifically, the SADS is a comprehensive list of questions that correspond to specific symptoms. The SADS and the RDCs are similar to the PSE in their emphasis on the length of time in which symptoms are present and in the presence of psychosis, which are required for the diagnosis of schizophrenia.

The diagnostic schemata of the PSE, the Feighner criteria, and the RDC also had a profound impact on the development of the most commonly used guideline for psychiatric nosology in the US, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), developed by the American Psychiatric Association. This manual has gone through several revisions. DSM-I and DSM-II, now of more historical interest, postulated a somewhat broad, glossary-like definition of schizophrenia. Later versions have relied on field trials and consensus diagnoses of collaborating specialists to narrow the definition, making this manual an important resource for researchers, clinicians, politicians, attorneys, patients, family members, and even third-party payers.

DSM-III, developed in the 1970s and published by the American Psychiatric Association in 1980, viewed schizophrenia much more narrowly, and for the first time in the DSM specific criteria were required for a diagnosis of schizophrenia. These included a minimal duration of symptoms, at least 6 months, which had also been a requirement in the Feighner criteria. This decision stemmed from a debate about whether shorter (less than 6 months) psychotic episodes that resolved quickly were considered the same disease entity as the more chronic and unremitting type of illness. In addition, DSM-III diagnostic criteria placed emphasis on the more easily validated Schneiderian concepts and included a multiaxial system of diagnosis.

The revised edition of DSM-III (DSM-III-R) was published in 1987. It was arranged similarly to its predecessor, that is, with a lettered list of criteria, broken down into numbered lists of specific symptoms. It incorporated some important changes, including the exclusion of transient psychosis by adding a one-week minimal presence of symptoms in criteria A, unless these symptoms were eliminated by treatment during that period. DSM-III-R also eliminated the maximal age at onset (45 years) for schizophrenia. This major modification was based on a lack of compelling data supporting an age restriction. In fact, since this change was implemented, several studies have demonstrated that the index episode of schizophrenia can occur at any age (see Howard et al. 2000). Along the same lines, onset in childhood was considered, and wording was changed to allow for the possibility of differential prognoses.

**Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition**

DSM-IV was released in 1994, to coincide with the publication of the *International Statistical Classification of Diseases*...
been simplified from earlier versions. The rest of the specific criteria, including criterion A and the criteria for the residual and prodromal syndromes, have been simplified from earlier versions.

In DSM-IV, criterion A of schizophrenia includes delusions, hallucinations, disorganized speech, disorganized or catatonic behavior, and negative symptoms. Two or more of these symptoms are required during the active phase of the illness. However, if the patient describes bizarre delusions or auditory hallucinations consisting of a voice commenting on the patient’s behavior or voices conversing, only one of these symptoms is required to reach the diagnosis. It is important to distinguish negative symptoms, which are often difficult to appreciate, from the myriad factors that may contribute to the severity and serious morbidity associated with schizophrenia. Patients who are not motivated to attend to their personal hygiene or suffer from alogia and a flattened affect are sadly at a disadvantage in society. The addition of negative symptoms as a separate criterion in DSM-IV recognizes the prominence of these symptoms in patients with schizophrenia.

### DSM-IV-TR Criteria

#### Schizophrenia

**A. Characteristic symptoms:** Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):

1. delusions
2. hallucinations
3. disorganized speech (e.g., frequent derailment or incoherence)
4. grossly disorganized or catatonic behavior
5. negative symptoms, i.e., affective flattening, alogia, or avolition

**Note.** Only one criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person’s behavior or thoughts, or two or more voices conversing with each other.

**B. Social/occupational dysfunction:** For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

**C. Duration:** Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

**D. Schizoaffective and mood disorder exclusion:** Schizoaffective disorder and mood disorder with psychotic features have been ruled out because either (1) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

**E. Substance/general medical condition exclusion:** The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

**F. Relationship to a pervasive developmental disorder:** If there is a history of autistic disorder or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

Criterion B addresses loss of social and occupational functioning, not exclusively because of any one of the items in criterion A. Patients may have difficulties maintaining employment, relationships, or academic achievements. If the illness presents at an early age, rather than as a degeneration or reversal of function, there may be a break from continued academic and social gains that are developmentally appropriate so that the person never achieves what had been expected.

Criterion C eliminates patients with less than 6 months of continued disturbance and again requires at least 1 month of the symptoms from criterion A. Criterion C allows prodromal and residual periods to include only negative symptoms or a less severely manifested version of the other symptoms of the A criteria.

Criterion D excludes patients who have a more compelling mood aspect of their illness and therefore their symptoms might instead meet criteria for schizoaffective disorder or a mood disorder. Both of these restrictions force a narrower view of the diagnosis of schizophrenia, which lessens the tendency of psychiatrists to overdiagnose schizophrenia.

Chapter 65 • Schizophrenia and Other Psychoses

Criterion E clarifies the fact that patients with schizophrenia are not suffering from other medical illnesses or the physiological effects of substances that might mimic the symptoms of schizophrenia. Finally, criterion F acknowledges that schizophrenia can be diagnosed in patients with autistic disorder or developmental disorder, as long as there have been prominent delusions or hallucinations that have lasted at least 1 month.

**DSM-IV-TR Subtypes of Schizophrenia**

In DSM-IV-TR, schizophrenia has been divided into clinical subtypes, based on field trials of the reliability of symptom clusters. The subtypes are divided by the most prominent symptoms, although it is acknowledged that the specific subtype may exist simultaneously with or change over the course of the illness. DSM-IV-TR also initiates an optional dimensional descriptor, which allows the condition to be characterized by the presence or absence of a psychotic, disorganized, or negative symptom dimension over the entire course of the illness.

**Paranoid Type**

In DSM-IV-TR, paranoid-type schizophrenia is marked by hallucinations or delusions in the presence of a clear sensorium and unchanged cognition. Disorganized speech, disorganized behavior, and flat or inappropriate affect are not present to any significant degree. The delusions (usually of a persecutory or grandiose nature) and the hallucinations most often revolve around a particular theme or themes. Because of their delusions, these patients may attempt to keep the interviewer at bay, and thus they may appear hostile or angry during an interview. This type of schizophrenia may have a later age of onset and a better prognosis than the other subtypes.

**Disorganized Type**

Disorganized schizophrenia, historically referred to as hebephrenic schizophrenia, presents with the hallmark symptoms of disorganized speech and/or behavior, along with flat or inappropriate (incongruent) affect. Any delusions or hallucinations, if present, also tend to be disorganized and are not related to a single theme. Furthermore, these patients would not be classified as having catatonic schizophrenia. These patients in general have more severe deficits on neuropsychological tests. According to DSM-IV-TR,
the same position for weeks at a time. Because of extreme mutism or agitation, patients may not be able to report any difficulties. Some patients may experience extreme psychomotor agitation, with grimacing and bizarre postures. These patients may require careful monitoring to safeguard them from injury or deterioration in nutritional status or fluid balance.

**Undifferentiated Type**

There is no hallmark symptom of undifferentiated schizophrenia; thus, it is the subtype that meets the criterion A for schizophrenia but does not fit the profile for paranoid, disorganized, or catatonic schizophrenia.

**DSM-IV-TR Criteria**

**Undifferentiated Type**

A type of schizophrenia in which symptoms that meet criterion A are present, but the criteria are not met for the paranoid, disorganized, or catatonic type.

**Residual Type**

The diagnosis of residual schizophrenia, according to DSM-IV-TR, is appropriately used when there is a past history of an acute episode of schizophrenia but at the time of presentation the patient does not manifest any of the associated psychotic or positive symptoms. However, there is continued evidence of schizophrenia manifested in either negative symptoms or low-grade symptoms of criterion A. These may include odd behavior, some abnormalities of thought processes, or delusions or hallucinations that exist in a minimal form. This type of schizophrenia has an unpredictable, variable course.

**DSM-IV-TR Criteria**

**Residual Type**

A type of schizophrenia in which the following criteria are met:

A. Absence of prominent delusions, hallucinations, disorganized speech, and grossly disorganized or catatonic behavior.

B. There is continuing evidence of the disturbance, as indicated by the presence of negative symptoms or two or more symptoms listed in criterion A for schizophrenia, present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

Cross-Cultural Definitions

Any diagnostic classification algorithm for an illness such as schizophrenia is necessarily limiting in its applicability to people of different cultures. Although its use allows some communication between mental health professionals internationally, there are bound to be distinct culturally acceptable definitions that may be more useful on a clinical level for a specific group of people. The ICD, now in its 10th revision, was developed by the World Health Organization to provide a means of collecting data regarding morbidity and mortality associated with health problems around the world. The chapter on mental illness, developed around the same time as DSM-IV, is easily understandable for those who are familiar with Western thinking. Yet the field of cross-cultural psychiatry is expanding. There is increased awareness of the need to work with patients within their own culturally diverse backgrounds. The classification schemes specific to local regions are often based on historical, religious, and traditional thinking unique to each setting.

As an example, in the psychiatric classification schemes in France, an important distinction has historically been made between transitory psychotic states (bouffée délirante) and what French psychiatry refers to as chronic delusional states. The latter are further subdivided into chronic interpretive psychosis, chronic hallucinatory psychosis, and chronic imaginative psychosis (Chabrol 2003). This has led to some confusion for those familiar with the ICD and DSM systems. Clinical differences are based on historical differences between the French and German Kraepelinian concepts, though more recent international classifications have reduced the discrepancies. The French characterization of a transitory psychosis has contributed in part to our conceptualization of brief psychotic disorder and schizophrenia (Chabrol 2003). As another example, Chinese psychiatric nosology and treatments based on a history dating back 3,000 years, are quite different from those in DSM and represent another example of cultural diagnostic differences. The original Chinese notions of mental illness were based, as in Western culture, on philosophy and religion. As Chinese medicine evolved, so did psychiatric concepts. The Chinese philosophy of yin and yang, or the opposing forces within all people, has predominated in the interpretation of psychiatric symptoms (Wig 1990). Other psychiatric traditions are based on mythological stories that have been passed from generation to generation.

One must avoid imposing Western definitions of psychosis on non-Western societies. Psychiatry and delusions, by definition, must be beliefs or experiences that are incongruent with those of the patient’s social or cultural background. An example of the difficulties in sorting through these matters is koro, which is the belief that one’s genitals are shrinking into one’s abdomen, based on Chinese mythology involving a fear of death. Although this is generally rare, there have been epidemics involving entire communities who have suffered from this condition. By Western standards, someone presenting with this symptom could be considered to have a psychotic or delusional disorder and even possibly be given a diagnosis of schizophrenia. A Western psychiatrist might fail to recognize that in some parts of Asia, this is within culture-bound limits and would be the equivalent of a neurosis as opposed to a psychosis.

In New Zealand, the Maori are well integrated with their European neighbors. While working in Westernized jobs, however, most continue to hold firmly to their Maori traditions. The differences in religious beliefs can lead to
difficult questions for mental health professionals, most of whom are of European descent. For example, Maoris who believe their relationship to the gods is unique, that they have been given special powers and messages from the gods to protect the Marae, or tribal community meeting place, may be within cultural norms and thus not meet any criteria for schizophrenia. In this context, the New Zealand government has long supported cross-cultural respect and communication and has created positions for cultural liaison specialists. These experts in Maori traditions are available to mental health teams to aid in decisions regarding diagnosis and treatment within a cultural context.

To determine where culture-bound beliefs end and delusions or inappropriate behaviors begin in a multicultural world is clearly not possible using only a written algorithm such as DSM-IV-TR. A critical step toward sound cross-cultural clinical care is developing an awareness of and a respect for diversity. Utilizing the expertise of persons familiar with a specific culture allows appropriate diagnosis and treatment of schizophrenia worldwide.

**Epidemiology**

**World Health Organization Studies**

Three major studies conducted by the World Health Organization (WHO) have provided clinicians and researchers with invaluable information regarding the epidemiology of schizophrenia. By utilizing consistent diagnostic criteria, having large sample sizes across several countries of diverse cultures and development, and including follow-up data, the WHO has collected a significant data set from which we can derive epidemiological information.

The first of these studies is known as the International Pilot Study of Schizophrenia and was conducted from 1969 to 1977. This study assessed 1,202 patients across nine countries (Taiwan, Colombia, Czechoslovakia, Denmark, India, Nigeria, UK, US, and former USSR) utilizing Wing’s Present State Examination, which was translated and back-translated to ensure consistency in diagnostic assessment across languages. A second major study, the Assessment and Reduction of Psychiatric Disability, examined social adjustment in 520 individuals with schizophrenia in seven countries (Taiwan, Colombia, Czechoslovakia, Denmark, India, Nigeria, UK, US) and 0.54 (US) per 1,000 people annually ranged from 0.15 in Denmark to 0.42 in India. This finding is corroborated by a review of the literature, in which the incidence of schizophrenia across 13 studies representing seven countries is found to range between 0.11 (UK) and 0.54 (US) per 1,000 people per year (Eaton 1985). Small variations in these incidence rates, because they are so low, have little meaning epidemiologically. Furthermore, the range of incidence rates for schizophrenia decreases significantly when consistent, tightly defined diagnostic criteria are employed.

Because schizophrenia is a chronic illness, the incidence rates must, by definition, be much lower than the prevalence rates. Prevalence is defined as the number of cases present in a specified population at a given time (e.g., at a specific point in time, during a time period, or over a lifetime). Lifetime prevalence represents the proportion of persons who have ever had the illness at a given time.

Lifetime prevalence rates of schizophrenia, based on the ECA data, were approximately 1% (range across three sites, 1–1.9%) (Robins et al. 1984). Point prevalence rates based on International Pilot Study of Schizophrenia data showed no significant differences across study centers: schizophrenia was found universally with relatively equal frequencies in a wide variety of cultures, though newer data described
below challenge this. Eaton’s review of the literature showed a range in point prevalence between 0.6 and 8.3 cases of schizophrenia per 1,000 persons in the population. The rate of schizophrenia per 1,000 persons fell within a similar range when looking at lifetime prevalence, point prevalence and period prevalence, which Eaton hypothesized was related to the fact that schizophrenia is a chronic but not fatal illness (Eaton 1985). In an update of Eaton’s review, it was noted that methodological differences may have partly accounted for statistical outliers in studies examining the incidence and prevalence of schizophrenia in different countries regardless of the type of prevalence. Specific studies of smaller populations, such as Helgason’s study of Iceland, found a 0.9% prevalence estimate (which approximates point prevalence rates) of schizophrenia (Helgason 1964). This study has been highlighted because it examined 99% of patients in a closed population and supports the findings of the larger studies such as the ECA study.

Interestingly, smaller studies have found specific populations with either a higher or a lower prevalence of schizophrenia. For example, a higher rate of schizophrenia has been found in a specific community in the north of Sweden, in northeastern Finland, in northwestern Croatia, and in western Ireland. Lower rates of schizophrenia have been found in, for example, parts of Tonga, Papua New Guinea, Taiwan, and Micronesia. In the US, schizophrenia was almost nonexistent in the Hutterite community, a Protestant sect living in South Dakota. Epidemiologists generally agree that these communities may represent aberrant findings. However, if these differences in prevalence rates are accurate, several theories have been offered as explanations, including genetic preloading, differences in diet, or even differences in factors such as maternal age. The evidence for a suggestion raised that there might be a decline in the incidence of schizophrenia was inconsistent and conflicting.

Since these earlier reports, newer epidemiological data from excellent studies have been surprising. The lifetime prevalence of psychotic disorders in Finnish adults was 3.48% with 0.87% for schizophrenia. Data from a recent review of 1458 incidence rates from 33 countries found up to 5-fold variations in incidence of schizophrenia between sites and a skewed distribution of rates challenging the notion created by WHO studies that schizophrenia is equally distributed (McGrath 2007). A meta-analysis used 1721 prevalence estimates from 188 studies with original data published between 1965 and 2002 and drawn from 46 countries with an estimated 154,140 potentially overlapping prevalent cases in a systematic review. Point prevalence (median) was 4.6 persons per 1000; 3.3 for period prevalence and 4.0 for lifetime prevalence (0.4%) for schizophrenia. These numbers are significantly different than those reported by other studies and appears that 4–8 individuals per 1,000, rather than higher numbers reported previously develop schizophrenia during their lifetime. Schizophrenia prevalence ranges from 4 to 7 per 1,000 with countries from the developing world having a lower prevalence of schizophrenia. The authors also report that this study highlights that symptoms persist despite the interventions offered. Different types of prevalence estimates had from 3.4 fold for point to 4.6 fold for period variation (Saha et al. 2005). This group further analyzed data to explore the effect of latitude on prevalence rates. Incidence of schizophrenia in men was significantly higher at higher latitudes (60° or more) and congruent with another study where there were winter/spring excess schizophrenia births at higher latitudes suggesting that men may be more vulnerable to the exposures related to latitudes and schizophrenia. The prevalence estimates of schizophrenia were significantly higher at higher latitudes when compared with lower latitude bands. Lifetime morbidity risk (LMR) was reported to be 7.2 per thousand. LMR attempts to include the entire lifetime of a birth cohort both past and future and includes those deceased at the time of survey. LMR is the probability of a person developing the disorder during a specified period of their life or up to a specified age. Based on cautious interpretation of the data, the prevalence of schizophrenia is reported to be lower in developing nations than in the developed ones. Questions are raised about the validity of the concept of equal incidence of schizophrenia across the world. Some but not all migrant groups have significantly higher rates of schizophrenia. There is an increased risk of schizophrenia associated with older paternal age, prenatal famine, winter/spring birth, higher latitude, prenatal infection, and pregnancy and birth complications.

Section VI • Disorders

Sociodemographical Characteristics

Age
One of the major changes from DSM-III to DSM-III-R was the abolition of the requirement for onset of symptoms before age 45 years for the diagnosis of schizophrenia. This led to more universal acceptance of the phenomenon of late-onset schizophrenia. DSM-IV and DSM-IV TR retained the revision made in DSM-III-R, and ICD-10 now includes paraphrenia (a term originally used by Kraepelin to signify a diagnosis distinct from dementia praecox in that the patients did not experience a deterioration) in a list of subtypes of schizophrenia instead of an independent diagnosis. Late paraphrenia subsequently came into favor to describe a paranoid delusional disorder with an onset usually after age 60 years. These changes in nomenclature and accepted nosological criteria have greatly affected epidemiological studies of schizophrenia and age at onset.

An investigation of late-onset schizophrenia found that 28% of patients had the onset of illness after age 44 years and 12% after age 63 years, based on 470 chart reviews of patients who had sought psychiatric help during a period of 20 years. Other studies have demonstrated that 23% of schizophrenia patients had an onset after their forties. The 1-year prevalence rate for schizophrenia in patients between 45 and 64 years of age was found to be 0.6% according to the ECA study. Furthermore, in a study of patients with onset after the age of 44 years, the majority of patients had symptoms that met all the criteria for schizophrenia found in DSM-III except for the age requirement, lending support to the need to discard the maximal age at onset limitation of DSM-III. Thus, although the majority of patients have an early age at onset, a certain subgroup of patients may have a disturbance that meets all the criteria of schizophrenia with onset in their forties or later.

The phenomenology of late-onset compared with early-onset schizophrenia may be distinct, with later-onset cases having a higher level of premorbid social functioning and exhibiting paranoid delusions and hallucinations more often than formal thought disorder, disorganization, and negative
symptoms. Studies have also shown a high comorbid risk of sensory deficits, such as loss of hearing or vision, in patients with late-onset schizophrenia. Specifically, late-onset patients are more likely to report visual, tactile, and olfactory hallucinations and are less likely to display affective flattening or blunting (Howard et al. 2000). For individuals over 65 years age, community prevalence estimates range from 0.1 to 0.5%. One of the most robust findings among the late-onset cases is the higher prevalence seen in women (Howard et al. 2000). This does not appear to be due to sex differences in seeking care, societal role expectations, or delay between emergence of symptoms and service contact. The International Late-onset Schizophrenia group has suggested a new classification system of late-onset schizophrenia (onset after the age of 44 years) and a very late-onset schizophrenia-like psychosis (onset after age 65) (Howard et al. 2000, Folsom et al. 2006).

“Late-life” schizophrenia includes those individuals who had their onset during adolescent or early adulthood and are now middle-aged as well as the late-onset schizophrenia patients (Folsom et al. 2006). Future studies will clarify how meaningful these categories are.

**Sex**

A large body of data suggests that although men and women have an equivalent lifetime risk, the age at onset varies with sex. Although some sites showed different prevalence rates of schizophrenia in men and women, the overall prevalence rates, as reported in the ECA survey, did not differ significantly between sexes. However, there is strong evidence that onset of schizophrenia is on average 3.5–6 years earlier in men than in women (Riecher-Rossler and Haefner 2000). The WHO 10-country study observed this phenomenon in most cultures studied. Therefore, incidence and prevalence rates of schizophrenia across sexes may vary according to age. Interestingly, in some cultural populations (e.g., West Ireland, Micronesia) the ratio of prevalence of schizophrenia for men could be as high as 2:1 (Myles-Worsley et al. 1999).

Recent epidemiological reviews have reported that the male-female rate ratios were 1.4:1 (see McGrath 2007). However, data from another systematic review did not confirm this (Saha et al. 2005).

Many studies have used criteria for schizophrenia that require onset before the age of 45 years, which also has accounted for some of the discrepancy in findings. There is undoubtedly a subgroup of patients who have a later onset of illness (after age 45 years), and this subgroup is made up predominantly of women (Howard et al. 2000). Among these female schizophrenia patients, there is a higher incidence of comorbid affective symptoms. When the effects of gender, premorbid personality, marital status, and family history of psychosis on the age at onset were removed in a reanalysis of WHO 10-country study data, there was a significant attenuation of the sex differences (Jablensky and Cole 1997).

**Race**

The ECA data have shown that there is no significant difference in the prevalence of schizophrenia between black and white persons when corrected for age, sex, socioeconomic status, and marital status. This finding is significant because it refutes prior studies that have shown the prevalence of schizophrenia to be much greater in the black population than in the white population. Adebimpe (1994) proposed several factors, including racial differences in help-seeking behavior, research populations, commitment status, and treatment, as explanations for some of these discrepancies. Efforts are being made to correct for some of these issues so that the epidemiological variables and heterogeneity of schizophrenia can be better understood in terms of race, whether black, white, Asian, or any other.

**Marital Status and Fertility**

A study of marriage and fertility rates of individuals with schizophrenia compared with the general population showed that on average, by the age of 45 years, three times as many of those with schizophrenia as of the general population are still unmarried (40% of men and 30% of women with schizophrenia are still single by age 45). Studies have also shown that fertility rates are lower in patients with schizophrenia compared with the general population. These observations may be related, and further investigation of the role of premorbid function, negative symptoms, and fertility rates, including rates among unmarried patients, is warranted. With the advent of the newer and more effective antipsychotic medications, and their increased use in first episode patients, it is possible that we may witness improved fertility and marriage rates in patients with schizophrenia.

**Socioeconomic Status**

For many years, epidemiological studies revealed a higher incidence and prevalence of schizophrenia in groups with lower socioeconomic status. With these findings came the hypothesis that lower social class could be considered a plausible risk factor for schizophrenia, possibly because of a higher risk of obstetrical complications, poorer nutrition, increased exposure to environmental toxins or infectious disease, or exposure to greater life stressors. In the past half century, studies have found that the actual incidence of schizophrenia does not vary with social class, based on first admission rates, adoption studies, and a series of studies examining the social class of the fathers of people with schizophrenia.

When these findings did not validate the original theory, it became clear that lower socioeconomic status was more a result than a cause of schizophrenia. This led to the acceptance of the downward drift hypothesis, which stated that because of the nature of schizophrenic symptoms, people who develop schizophrenia are unable to attain employment and positions in society that would allow them to achieve a higher social status. Thus, these patients drift down the socioeconomic ladder, and because of the illness itself they may become dependent on society for their well-being.

**Immigration**

Epidemiological studies of immigrant populations in the early part of the 20th century led to the supposition that the stress of immigration increased the risk for psychosis. However, further investigations of acculturation as a risk factor for schizophrenia have yielded mixed results. The opposite idea, that having a mental illness increased the likelihood of emigrating, has also been reviewed (Eaton 1985). At this time, there is no conclusive evidence that emigration increases the risk of schizophrenia. Furthermore, immigration screening has become more rigorous since the earlier
studies, and legal immigrants may therefore be less likely to have increased risk for developing schizophrenia.

The remarkably high incidence and prevalence rates of schizophrenia observed in second-generation Afro-Caribbean, and Suriname and Dutch Antilles migrants to the UK and Netherlands respectively are baffling. These findings have been replicated and data from 17 studies show a wide range of relative risk from 1.7 to 13.2 (Eaton and Harrison 2000). A recent systematic review suggests that migrants were more likely to develop schizophrenia than native-born individuals (median risk ratio = 4.6). These findings were confirmed by Saha et al. (2005) too. Diagnostic bias, misclassification, or biological risk factors do not account for these findings. Thus, environmental risk factor(s), currently unknown, have been proposed to underlie these phenomena. The relationship between migration and schizophrenia is complex and needs further clarification (Bhugra 2000).

**Industrialization**

With the increasing presence of the mentally ill on the streets of modern urban locations, the question has often been raised of whether urban life, or industrialized society, is a risk factor for the development of schizophrenia. In fact, there seems to be data suggesting that people in urban areas have a higher relative risk for schizophrenia than those in rural areas or mixed urban/rural sites. However, in the larger study by the same group, prevalence did not differ according to urbanicity (Saha et al. 2005). Torrey and colleagues (1997) reanalyzed the US 1880 census data and found that urban residence was associated with a higher risk for psychosis. Marcelis and colleagues (1998) analyzed all first admissions for schizophrenia and other psychosis in Holland between 1942 and 1978 by place of birth and found a statistically significant relationship between size of urban areas and incidence of schizophrenia, affective, and other psychosis. Furthermore, in the WHO follow-up studies of the International Pilot Study of Schizophrenia, there was a significant difference in the course of schizophrenia between industrialized and developing nations, with individuals with schizophrenia in developing countries having a less severe and less chronic course of the illness.

Various explanations for these discrepancies have been postulated. For example, in industrialized areas the family structure may impose more social stresses on the ill relative, who is often unable to work and perform by society’s standards, whereas in developing countries the family structure may be protective, with other relatives supporting the ill relative. Another possible explanation is a selection factor in developing countries resulting from the higher infant mortality in nonindustrialized societies. According to this hypothesis, children in less developed countries who would be at risk for schizophrenia would not be as likely to survive, thus skewing the prevalence rates of schizophrenia in these areas. However, some suggest that this risk factor of increase incidence of psychosis in urban areas is more ecological than genetic. Further investigation is needed to provide definitive answers as to why schizophrenia may have a higher prevalence and more severe course in industrialized nations.

**Season of Birth and Onset**

That season of birth differs between individuals with schizophrenia and the general population has by now gained wide acceptance. This factor has been studied in the 20th century, with the predominant view that the birth rate of people with schizophrenia is highest in late winter (Eaton 1985). Torrey and colleagues (1997) confirmed this, reviewing approximately 250 studies and concluding that there is an excess of schizophrenia births during winter. In fact, there is approximately a 5–8% greater likelihood for individuals with schizophrenia to be born during winter months compared with the general population. This higher incidence of winter births has been found in both hemispheres, offering further evidence that this phenomenon is related to the colder months rather than specific calendar months.

It is clear that even though only a small proportion of all those with schizophrenia are born during winter months, the deviation from the seasonality of birth of the general population (the number of general births peaks in the spring) is a striking phenomenon. This finding is not unique to schizophrenia, and differences in seasonality of birth have been described for mania, diabetes mellitus, Down syndrome, congenital hip dislocation, and certain cardiovascular malformations. It is therefore debatable whether this observation has etiological significance unique to schizophrenia.

Season of onset has also been considered in epidemiological investigations of schizophrenia. A preponderance of data dating back to the early 1800s indicates that the summer season is associated with a higher incidence of the onset of symptoms. Suicide rates also vary according to season, with a spring peak, indicating that the interaction of environment and psychopathology may be of some significance. Recent reports of excess of summer births in patients who have deficit sub type of schizophrenia raises some interesting possibilities.

**Morbidity and Mortality**

The economic costs of schizophrenia have been estimated to be six times the costs of myocardial infarction. The WHO has estimated that mental illness accounts for as much as two-fifths of all disability funding in the US. Amongst the homeless in New York City, a significant percentage of costs of hospital admissions were associated with schizophrenia patients. In the US, the cost of schizophrenia in 1994 was $44.9 billion and rising. In the UK, 5.4% of total National Health Service inpatient costs were attributed to schizophrenia. When all services were combined together, approximately £2.6 billion were spent annually taking care of schizophrenia patients. In Australia, it is estimated that schizophrenia costs approximately $3 billion for treatment and due to lost productivity (Mowry and Nancarrow 2001). Much of the cost of schizophrenia is due to the high morbidity of this chronic illness. Premorbid deficits, cognitive deficits, and negative symptoms account for much of the disability. Also, schizophrenia patients with more severe courses may require repeated hospitalizations and may not be capable of maintaining independent living or stable employment.

The mortality rate of schizophrenia is estimated to be twice that of the general population. Approximately 10% of the mortality is secondary to suicide. Young male patients with schizophrenia are most likely to complete suicide attempts, especially early in their illness. Degree of social isolation, agitation, depression, a sense of hopelessness, a
disorders that are associated with human leukocyte antigens (HLA). The associated risks for these disorders and schizophrenia have led to speculation that certain subtypes of patients with schizophrenia may be manifesting symptoms related to an autoimmune process. For example, studies have shown that there may be an association between HLA types and schizophrenia. In one recent study, the HLA frequency was increased for HLA A10, A11, and A29 and decreased for HLA A2 in patients with schizophrenia (Ozcan et al. 1996). Thus, although the presence of HLA is not universal among persons with schizophrenia, further investigation into this area may point to alternative hypothesis regarding etiology and treatment of a certain population of patients with schizophrenia.

Reversing the association, there are numerous medical illnesses with symptoms similar to those of schizophrenia. Among examples of these, the most common neurological disorder appearing clinically similar to schizophrenia is epilepsy, particularly of the temporal lobe. Other medical illnesses with symptoms similar to those of schizophrenia include basal ganglia calcifications and acute intermittent porphyria. Imbalances of endocrine function as well as certain infectious diseases can present with symptoms that mimic schizophrenic psychosis. Further investigation of these illnesses may lead to a greater understanding of the pathophysiology of schizophrenia.

**Etiology**

The cause(s) of schizophrenia currently remain unknown. However, fast-paced developments in neuroscience combined with advances in psychiatric research have resulted in increased optimism about discovering the cause(s) and delineating the pathogenesis and pathophysiology of this mysterious illness. A leading view is that schizophrenia may be heterogeneous with respect to etiology. Thus, multiple causative mechanisms may give rise to distinct disease subtypes. If this is true, it is important for psychiatric researchers to differentiate the homogeneous subtypes of this illness. Moreover, it has been proposed that more than one causative mechanism might interact (the so-called double-hit hypothesis) to cause the illness in some individuals. Available data strongly indicate that the interactions between genetic and environmental factors may lie at the core of this illness. In this section, the main etiological theories of schizophrenia are examined.

**Genetics**

Schizophrenia represents a daunting challenge for genetic researchers for several reasons: the paucity of extended multigenerational family histories containing large numbers of affected individuals; the increasing evidence of genetic heterogeneity, such as more than one phenotype or more than one genetic variant; a lack of agreement on the mode of transmission; and the genotype-phenotype relationship might be more symptom- than diagnosis-based. Following genetic modeling of epidemiological data and the results of several genome screens for susceptibility genes, the probability of schizophrenia being a single gene disorder is unlikely. The probability that several genes of large effects may confer vulnerability to schizophrenia is diminishing too. Thus, the focus has shifted to multiple genes of small to moderate effects which may compound their effects through interactions with each other and with other nongenetic risk factors.
A reanalysis of these data in the late 1980s confirmed the schizophrenia had higher rates of schizophrenia in their relatives of adoptees with schizophrenia. Danish adoption studies conducted in the 1960s compared in relatives of adoptees with and without schizophrenia. In these studies, the rates of schizophrenia are up to 10 times greater among these individuals than in individuals with no first-degree relatives with schizophrenia. There is approximately six times and two times greater chance of developing schizophrenia in second- and third-degree relatives of individuals with schizophrenia (Tsuang et al. 2001). In addition, the higher prevalence of schizophrenia spectrum disorders among family members of individuals with schizophrenia, such as schizoaffective disorder and schizoid and schizotypal personality disorders, provides support for a common genetic basis for this family of schizophrenia-like illnesses. Different studies have provided evidence for and against an increased prevalence of other psychotic disorders and nonpsychotic affective illnesses among relatives of persons with schizophrenia.

Adoption Studies
Adoption studies constitute a powerful experimental strategy for examining the role of genetic versus environmental factors. In these studies, the rates of schizophrenia are compared in relatives of adoptees with and without schizophrenia. Danish adoption studies conducted in the 1960s and 1970s provided compelling evidence that adoptees with schizophrenia had higher rates of schizophrenia in their first-degree relatives than control adoptees (Kety 1987). A reanalysis of these data in the late 1980s confirmed the original finding that biological relatives of schizophrenia adoptees had significantly higher rates of schizophrenia (4.1%) than biological relatives of nonschizophrenia (control) adoptees (0.5%).

In Finland, a large study of adopted-away offspring of mothers with schizophrenia found that significantly more offspring of mothers with schizophrenia themselves developed schizophrenia (9.1%) than did control offspring (1.1%). An interesting aspect of the Finnish study was the examination of family environment in the adoptive families. A relationship was found between a disruptive family environment and occurrence of schizophrenia in adoptees. This suggests that environmental factors might play a role in the manifestation of the illness in genetically susceptible individuals. However, the study did not make clear whether the schizophrenia adoptee caused the disruptive home environment or the disruptive environment contributed to the manifestation of the illness. Longitudinal assessment of environmental conditions throughout childhood before the onset of illness will be important in resolving this issue.

Several methodological issues are important in interpreting the data from adoption studies, including the diagnostic status of biological fathers and levels of psychopathology in adoptive families. Additional factors to consider are the intrauterine environment, birth complications, and length of time from birth to adoptive placement.

Twin Studies
Another approach to examining genetic contributions to schizophrenia involves concordance studies of dizygotic (nonidentical) and monozygotic (identical) twin pairs. Available data indicate that the concordance of schizophrenia among dizygotic twins is approximately 8–12%. This is much greater than the 1% rate found in the general population and comparable to the rate of concordance of schizophrenia among first-degree siblings. The concordance of schizophrenia among monozygotic twins is approximately 50%. Even though the high rate of concordance among monozygotic twin pairs is compelling evidence for genetic contributions, the fact that it is not higher than 50% suggests a role for additional, perhaps nongenetic, factors in the etiology of schizophrenia. Moreover, although monozygotic twins share the same genetic information, it is possible for a mutation to occur in one member of the twin pair and not the other. Birth order of twin pairs and different intrauterine effects are other factors to consider. An attractive and robust experimental design is provided by adoption of monozygotic twin pairs, which effectively combines the strengths of both adoption and twin methodologies. The number of sets of adopted-away, monozygotic twin pairs affected with schizophrenia is relatively small. However, data available on the limited number of pairs meeting these criteria support the strong concordance of schizophrenia in monozygotic twins.

Linkage and Association Studies
There was tremendous enthusiasm and hope riding on the two promising approaches to identify the faulty gene(s) responsible for schizophrenia: linkage studies and association studies. Linkage studies use polymorphic genetic markers to attempt to identify statistical agreement (known as a logarithm of the odds score) between the presence of the marker and illness in families under investigation. It should be noted that genetic markers mark a segment of DNA presumably where the gene of interest resides; they do not necessarily identify mutant genes themselves. Once linkage is established, the second stage of work begins, which entails searching the identified segment of DNA for the faulty gene. However, the linkage studies have a limited power to detect susceptibility genes of small effect, a most likely scenario in complex disease genetics such as schizophrenia. This can be overcome by association studies (Lichtermann et al. 2000).

Association studies actually use the candidate genes themselves and test the highly specific hypothesis that a mutation in the candidate gene occurs at a greater rate in the population of interest (in this case schizophrenia patients) than in nonaffected control populations. More recently, family based samples such as trios (consisting of the affected person and both parents, if available), are collected to avoid population stratification. One limitation of this approach is that it is all or none; that is, the candidate gene either is or is not associated with the illness. With enormous resources and efforts dedicated to uncover genetic underpinnings of schizophrenia and lack of commensurate progress, questions were being raised if schizophrenia’s phenotypic variability has confounded the search for its causes. Specifically, the inconsistent and poorly replicated results of genetic linkage and association studies.
using the current diagnostic category as the sole schizophrenia phenotype was disheartening. However, the Human Genome Project with its approximately 23,000 genes provided just the platform to search for schizophrenia genes. Recent discoveries of genes for schizophrenia were made possible through a successful genome-wide search using linkage analysis to map genes in broad candidate areas. This was followed by identification of susceptibility genes within this region by either systematic narrowing down or by trial and error. Three genes that emerged as strong candidates for susceptibility genes are the dysbindin gene on chromosome 6p (DTNBP1), the neuregulin-1 gene on chromosome 8p (NRG1), and DAOA (previously called G72/G30) gene on chromosome 13q. Remarkably, for each of these genes a majority of the studies have reported significant associations with markers and/or marker combinations (haplotypes). Linkage and association studies have now implicated these and several other loci in the genome that appear likely to harbor genes conferring risk for schizophrenia (see Table 65–1 and Figure 65–2).

These events have infused a new-found enthusiasm and optimism in the field. Thus, linkage strategy has proven to be ideal for finding regions containing major effect genes that follow identifiable inheritance patterns in families. What seemed difficult to do previously has now occurred with a sizeable set of confirmed linkage regions, some of which are strong enough to withstand rigorous correction for whole genome analysis (e.g. 1q, 6p, 6q, 15q) and others have been supported by meta-analysis (8p, 13q, 22q, etc.) (see Table 65–1 and Figure 65–2). Linkage has been partly successful because linked regions contain multiple susceptibility genes and thus, within a linkage sample, different genes segregating in different families can contribute to the linkage signal for that region. Additionally, linkage approach also benefited greatly from the presence of multiple susceptibility genes being present even up to 20 centimorgans apart. An example of this would be chromosome 6p22–24, where dysbindin MUTED and MRDS1 are located within 10 megabases of each other. Surprisingly, even among some of the most consistently replicated genes (e.g. dysbindin NRG1, DAOA), the associated alleles and haplotypes differ considerably across studies. Many believe that a unifying and simplifying approach, based on characterizing the functional state of the gene, is going to be one of the most productive ways to evaluate genetic effects (see Straub and Weinberger 2006 and Maier et al. 2006).

Neuregulin 1 (NRG1) was identified as a candidate gene via fine-mapping of a locus on chromosome 8p21–22 linked to schizophrenia in Iceland and replicated in other countries too. No functional polymorphisms have been identified yet. NRG1 signaling, via ErbB receptors and regulation of both NMDA receptors and postsynaptic density 95 (PSD-95), has been implicated in neuronal differentiation and migration. While the functional role of NRG1 in schizophrenia is not clear, postmortem studies suggest that NRG1 signaling may be enhanced in schizophrenia leading to suppression of NMDA receptor function consistent with the glutamate hypofunction hypothesis of schizophrenia (see below).

Dystrobrevin Binding Protein 1 or Dysbindin is linked to chromosome 6p and is widely distributed in brain and has been detected both pre and postsynaptically including in the synaptic terminal in the hippocampus. It is thought to influence glutamate neurotransmission. Dysbindin has also been connected with the glutamate hypofunction hypothesis. Dysbindin has been associated with negative symptoms of schizophrenia and also possibly prefrontal brain function.

D Amino Acid Oxidase Activator (DAOA) gene is located on chromosome 13, DAOA activates D Amino Acid Oxidase (DAO) which oxidizes D-Serine, which is a coagonist at NMDA glutamate receptors. Again, there may be a connection here with the Glutamate hypothesis (see Ross et al. 2006 for more details).

Using alternative strategies where cytogenic analyses in isolated families highly loaded with schizophrenia was pursued, a balanced (1:11) chromosomal translocation was detected to cosegregate. A specific gene which was not previously known on chromosome 1 was regularly disrupted and

was named DISC1. Now, DISC1 is emerging as the best supported candidate gene for schizophrenia. DISC1 segregates with schizophrenia, bipolar disorder, and other major mental illnesses in a large pedigree in Scotland with LOD scores of 7. The translocation is between exons 8 and 9 of the DISC1 gene on chromosome 1. DISC1 appears to have roles in both brain development and adult neuronal functioning. Developmental roles include regulation of neuronal migration, neurite outgrowth and neuronal maturation. In adults it may modulate cytoskeletal function, synaptic transmission and plasticity. DISC1 interacts with several proteins implicated in neuropsychiatric diseases and possibly related to cortical development (see Ross et al. 2006, Maier et al. 2006).

Another successful alternative strategy is based on the principle that gene expression might guide to susceptibility genes. Abnormalities in synaptic and postsynaptic transmission are assumed to be a crucial feature of schizophrenia. Phosphokinases present as a family of candidate proteins involved in intracellular signal transmission and are coded by polymorphic genes; these have become ‘hot’ candidate genes. These DNA-sequence variants in the differentially expressed protein kinase B (AKT1) were found to be associated with schizophrenia (Maier et al. 2006).

Weinberger and colleagues (2001) suggested that the gene that encodes the postsynaptic enzyme catechol-o-methyl transferase (COMT) is preferentially involved in the metabolism of dopamine in frontal lobe and is located on chromosome 22q–11. Dopamine is hypothesized to underlie aspects of cognition in frontal lobe such as information processing. Based on animal studies, family-based association studies, and fMRI studies in schizophrenia patients and general population, Weinberger and colleagues proposed an interesting hypothesis that the COMT genotype with valine allele (val/val type) may increase the risk of developing schizophrenia due to its effect on dopamine-mediated prefrontal information processing. However, a recent meta-analysis did not find an association between Val-variant of the COMT gene and schizophrenia. In the case of COMT, a gene has defined consistent association to its common functional coding val/met variant, likely because other functional variants in the gene have evolved to balance the effect of this polymorphism. The association between COMT alleles and schizophrenia appear to be less striking than the association between COMT and cognitive function. Variation at the COMT locus may provide the best studied example of the relationship between variation at the genetic locus and the endophenotype closely related to schizophrenia (Ross et al. 2006). The interaction between COMT val/met genotype and early adolescent cannabis use is interesting. While COMT genotype alone had no predictive effect on the emergence of schizophreniform illness by age 25, in combination with early marijuana use, the risk odds ratio for the val/val genotype was 10-fold greater than in the general population (Straub and Weinberger 2006).

A strong genetic association between schizophrenia and the chromosomal microdeletion syndrome, velocardiofacial syndrome (VCFS), caused by deletion of 1.5–3 Mb in chromosome 22q–11 has been postulated. Approximately 20–30% of patients with VCFS have schizophrenia or other major psychiatric disorder with psychosis. Patients with schizophrenia have increased frequency of the microdeletion compared with the general population. The VCFS region includes at least 27 genes including COMT. VCFS patients have facial dysmorphism and other features, and presumably are caused by loss of one copy of several or many genes in this region. The VCFS or Di George syndrome occurs with a frequency of approximately 1 in 6,000 births. Schizophrenia patients with VCFS have more severe cognitive deficits of spatial working memory, visual recognition, and attention than VCFS. Compared to matched normals, schizophrenia patients with VCFS have smaller total grey matter volume, larger lateral ventricles, and decreased gyrification in the frontal and parietal lobes (Jablensky 2006). The risk of schizophrenia is three times higher in people with learning disability than in the general population and chromosomal variants and abnormalities are increased. Structural MRI in these individuals reveals abnormalities of the hippocampus and amygdala that are more severe than in people with schizophrenia alone and very different from people with learning disability alone. VCFS is associated with learning.

**Figure 65-2 Locations of linkage findings and genes.** (Source: Owen MJ, Craddock N, and O’Donovan MC [2005] Schizophrenia: Genes at last? Trends in Genetics 21(9), 518–525.)
disability also. The associated phenotype is highly variable with congenital heart defects occurring in approximately 75% patients (Muir et al. 2006).

Modern functional genomic approaches such as DNA microarrays, based on the principles of nucleic acid hybridization, can check a tissue sample for presence of thousands of genes simultaneously. For example, Mirnics and colleagues (2000) employed cDNA microarrays and compared transcriptomes in schizophrenia and matched control subjects and found that only a few gene groups consistently differed between subjects and controls. In all subjects with schizophrenia, the most changed gene group was related to presynaptic group secretory function (PSYN) gene group and in particular the “mechanics” of neurotransmitter release. Thus, Mirnics and colleagues (2000) postulated that, as the most affected genes in the PSYN group varied across study subjects (suggesting that the illness has “distinct molecular signatures”), schizophrenia, therefore, may involve a combination of different sequence-related polygenic susceptibility factors and physiological adaptations that lead to impairment of the signaling between neurons. They found additional support for their hypothesis from reports of reduced expression of regulator of G-protein signaling 4 (RGS4) in individuals with schizophrenia. In the brain, RGS4 is one of the 30 or more RGS family members that serve as GTPase-activating proteins (GAPs), which reduce response duration of postsynaptic neurons after the release of presynaptic neurotransmitters that bind to G-protein coupled receptors. Thus, Mirnics et al. (2001) suggested that the deficits in PSYN and RGS4 expression may produce synaptic changes with pathophysiological consequences relevant to schizophrenia. RGS4 is located on chromosomal region 1q21–22. Stress and other environmental factors appear to regulate this gene. Levitt et al. (2006) further suggests that RGS4 may be a molecule that may underlie increased vulnerability through genetic as well as environmental mechanisms.

It should not come as a surprise that many genes identified so far appear to impact biologically on some of the most basic processes of brain development, involving neuronal differentiation, synapse biology and various processes involved in neuronal plasticity. With the exception of DISC1, all known susceptibility genes code for synaptic proteins. This is not surprising as there is reduced dendritic spine density in the cortex and hippocampus of schizophrenia patients and diminished levels of synaptic markers such as synaptophysin and the complexin proteins have been observed consistently. Glutamate and GABA are fast transmitters. PRODH (Prolin Dehydrogenase) and DAOA code for proteins involved in glutamate signaling while the neuregulin-1 receptor ErbB forms a functionally important complex with glutamate NMDA receptors. Dysbindin is involved in the vesicular release of glutamate in the schizophrenic hippocampus, dysbindin immunoreactivity is diminished at glutamate terminals and mRNA and protein are decreased in schizophrenic prefrontal cortex (Morrison and Murray 2006). These are positive and hopeful developments. Clearly, faster, innovative, and sophisticated techniques have ushered genetic research into a new era with a renewed promise to explore genetic basis of mental illnesses.

Researchers are urgently searching for schizophrenia phenotypes for subgroups or dimensions that may define etiologically or genetically distinct subtypes. Similarly, the field is yearning for endophenotypes with simpler architecture than schizophrenia to possibly guide to newer leads in research (Mowry and Nancarrow 2001). Latent genetically influenced traits, which may be related only indirectly to the classic disease symptoms defined in major classification systems are known as “endophenotypes.” They reflect an underlying susceptibility to the disease phenotype (or some form of it). In schizophrenia we are interested in endophenotypes that are measurable by neurophysiological or neuropsychological means. Crucial characteristics of any endophenotype include the fact that it can be measured before the explicit onset of the illness, and that it represents the genetic liability of nonaffected relatives of probands with the disorder. For example, in genetically complex disorder such as schizophrenia, could separate genetic loci contribute to distinct aspects of the illness phenotype (e.g., evoked potentials, aspects of cognition, etc.)?

Patients with schizophrenia have been shown to have deficits in sustained attention as measured by P50 and other information processing tests. Genome-wide linkage analysis showed that the P50 gating information processing deficit is heritable in families with schizophrenia and maximal linkage was at the chromosome 15q–14 locus of alpha-7 nicotinic acetylcholine receptor gene (Freedman et al. 2001). Polymorphisms in the gene and its nearby partial duplication are associated with diminished P50 inhibition and cognitive dysfunction. These data along with other converging lines of evidence including post mortem studies have strongly implicated the alpha-7 nicotinic receptor in the pathophysiology of schizophrenia and provides an intriguing potential target for novel therapeutics for this illness.

When the test for associations of at-risk haplotypes and at-risk alleles for schizophrenia were done in bipolar disorder, the DAOA and the NRG1 genes were found to be implicated in the etiology of bipolar disorder along with variants of dysbindin gene. Does this favor a common predisposing susceptibility allele? To answer this question, associations with the same haplotype/marker in schizophrenia and in bipolar disorder in the same population were done by Schumacher et al. (2004), and Green et al. (2005), and the data were able to support the possibility for the DAOA and the NRG1 gene respectively. A similar pattern is emerging for DISC1. A refined analysis proposed ‘persecutory delusions’ to explain the association between the DAOA haplotype and bipolar disorder and NRG1 with mood incongruent psychotic features. Thus, questions are being raised as to what is the more appropriate clinical target for an involved susceptibility allele or haplotype, core symptoms or criteria driven diagnosis? Maier et al. (2006) observe that it is remarkable how all risk genes identified for schizophrenia and bipolar disorder involve glutamatergic transmission or development of neurons and glial cells. These observations point to cross-diagnostic communalties in glutamatergic transmission and neurodevelopment (see Maier et al. 2006). Furthermore, DTNBP1 at-risk haplotype is preferentially associated with negative symptoms. Although diagnostic categories are useful to detect susceptibility genes, the genotype-phenotype relationship might be more symptoms- than diagnosis-based. Thus, future developments in genetics are quite likely to have an impact on the nosology of schizophrenia and psychiatry.
Viral Hypotheses

The suggestion that psychotic illnesses may be related to an infectious process has a long history. Jean Étienne Esquirol in 1845 noted that some forms of psychotic illness followed “epidemic” illness patterns. In the early part of this century, Karl Menninger observed an association between the onset of schizophrenia and influenza epidemics. In addition, it has long been known that clinical features of viral encephalitis may include psychosis and other features resembling those of schizophrenia.

Two lines of evidence that have provoked the most interest in the possibility that viral infections are causative of schizophrenia are an increase in birth during influenza epidemics of individuals who subsequently develop schizophrenia and an increase in winter births among patients with schizophrenia because of the higher rate of viral infections in winter months. Mednick and colleagues (1988) reported a strong association between pregnancies during the 1957 influenza epidemic in Helsinki, Finland, and subsequent development of schizophrenia. Moreover, it was learned that the relationship between viral exposure and schizophrenia appears strongest when exposure occurred during the second trimester of pregnancy. This is of interest because the second trimester is a critical period for cortical and limbic development. It was therefore reasoned that second-trimester viral exposure might disrupt neuronal development in key areas of the brain, such as the hippocampus and prefrontal cortex that have been implicated in this illness. In fact, there is some experimental evidence from animal models that viral exposure to these regions in the developing brain produces neuropathological changes resembling those observed in some postmortem studies of schizophrenia. However, reanalysis of previous data failed to detect significant association between in utero exposure to influenza epidemics and schizophrenia. Similarly, data from Australia failed to find an association between six influenza epidemics and schizophrenia (Morgan et al. 1997). These and other negative results have raised serious questions about this theory. Interestingly, in the North Finland birth cohort, a significant association was found with laboratory confirmed diagnosis of viral infection, especially Coxsackie B5 meningitis in the neonatal period and risk of schizophrenia later on.

As previously mentioned, several studies have demonstrated an excess of winter births among patients with schizophrenia. Although statistically significant, the association between winter births and schizophrenia appears relatively small, occurring in less than 10% of cases. Thus, season of birth remains an interesting (and unresolved) research issue but has little use as a risk factor for the illness from a clinical perspective. However, exposure to influenza in utero and excess winter births is interesting although indirect lines of evidence for a viral cause of schizophrenia. To date, there has been no direct confirmation for any viral agent causing this illness, such as viral isolates or consistent findings of specific viral antibodies. Advances in neurovirology, however, are providing new insights into the role of viruses in brain diseases, leading to new hypotheses about schizophrenia. One area involves the search for neurotropic retroviruses. For example, Borna virus is a naturally occurring neurotropic agent in horses and sheep. The development of a serological assay method to detect antibodies for Borna virus led to the discovery that its hosts also include humans and that it has relative tropism for the hippocampus. Moreover, its clinical manifestation range from clinical symptomatology to profound behavioral abnormalities that resemble some aspects of schizophrenia. An association between deficit symptoms, Borna virus antibodies and summer birth excess has been reported. There is now an active research effort to determine whether Borna and other neurotropic viruses are more common in schizophrenia. Torrey et al. (2006) are making a similar case for cytomegalovirus (CMV) to play an etiological role in schizophrenia using CMV antibodies in first episode patients. However, in infections that have been associated with schizophrenia such as rubella, influenza, Herpes Simplex Virus-1 and -2, cytomegalovirus, poliovirus, and toxoplasma gondii, it is not the virus itself that adversely affects fetal brain development, but rather the cytokine response from the infected mother. Moreover, infections during pregnancy can affect brain development by releasing stress hormones, producing hypoxia, hyperthermia or malnutrition or by triggering proinflammatory cascade of cytokine responses of the mother, placenta, or the fetus (Ross et al. 2006).

Immune Dysfunction

Several research groups are exploring the possibility that schizophrenia may be associated with impaired immune function including alterations in autoimmunity. According to a recent report, a history of any autoimmune disease was associated with a 45% increase in schizophrenia, thyrotoxicosis, Sjogren’s disease, celiac disease, acquired hemolytic anemia and interstitial cystitis (Eaton et al. 2006). Anticardiolipin antibody and antinuclear antibody, two autoantibodies that are used as markers of autoimmune vulnerability, have been shown to be increased in patients with schizophrenia in some but not all studies of this illness. Specific histocompatibility antigens (human leukocyte antigens) have also been linked to several autoimmune diseases and have been investigated in schizophrenia with conflicting results. Two other markers relevant to autoimmunity function, impaired T lymphocyte proliferative response to the mitogen phytohemagglutinin and impaired interleukin-2 production, have shown more consistent alterations in patients with schizophrenia than in control populations. Interestingly, an inverse relationship exists between rheumatoid arthritis and schizophrenia. This has been explained by some as both illnesses sharing a common immune etiology such that once an individual is affected by one of the diseases, they become relatively immune to the other. Some of the most intriguing work in this area is focused on finding autoantibodies to brain tissue. Recent reports of atypical antipsychotic medications having immunomodulatory effects and selective COX-2 inhibitor (a nonsteroidal anti-inflammatory pain killer) having positive effects on schizophrenia symptoms are interesting and provide yet another avenue of research in understanding the complexity of schizophrenia. Immunological aberrations have been associated with clinical symptomatology in several studies with paranoid symptoms, negative symptoms, and acute symptomatology (Strous and Shoenfeld 2006).

Birth Complications

Numerous studies have reported a higher rate of pregnancy and birth complications in patients with schizophrenia than in control populations (Cannon et al. 2002). The complication rates vary widely among studies, probably because
of the inherent difficulties in obtaining reliable and valid retrospective data in this area. In one study, two-thirds of schizophrenia patients and less than one-third of control subjects had histories of obstetrical complications. Hypoxia is one possible result of pregnancy and birth complications that has been shown to disrupt brain development. The hippocampus and some neocortical regions are particularly sensitive to shortfalls in oxygen. Thus, one proposed mechanism for a role of pregnancy and birth complications in the cause of schizophrenia involves hypoxia-mediated damage to these areas. While some investigators agree with this theory, others do not. Interestingly, some studies suggest that the rate of obstetric complications are higher in early-onset schizophrenia, occur more often in males, in people with prominent negative symptoms, and no family history of schizophrenia (Verdoux et al. 1997). Rhesus (Rh) factor incompatibility between mother and fetus leads to increase risk for schizophrenia (OR up to 2.6). It is not clear if this is due to hypoxia or increase in bilirubin levels or both.

A metaanalysis of data involving 854 individuals from 11 research groups (Verdoux et al. 1997) suggests that the relationship between birth complications and age at onset tend to be linear and may indicate a causal effect. Jones and colleagues (1998), using North Finland birth cohort involving 11,017 patients reported a sevenfold excess among schizophrenia patients of perinatal brain injury. In a historical and meta-analytic review by Cannon and colleagues (2002), complications of pregnancy, abnormal fetal growth and development and complications of delivery were significantly associated with developing schizophrenia but the effect sizes were generally small with odds ratios of less than 2. Diabetes in pregnancy (OR = 7.76), placental abruption (OR = 4.02) and birth weight of <2,000 gm (OR = 3.89) had higher odds ratios. They elaborate current methodological shortcomings and suggest need for newer and better approaches to inform our understanding of these important associations (Cannon et al. 2002). Recently, they proposed to group birth complications based on similar modes of action and suggested following categories: fetal growth retardation, fetal perinatal hypoxia and prenatal complications. They conceptualize fetal growth retardation as one of the earliest manifestations of the neurodevelopmental trajectory of schizophrenia that includes decrements in motor, language, and cognitive performance from infancy throughout childhood. Furthermore, based on work done by them and others, the intriguing interactions between fetal hypoxia and genetic risk for schizophrenia on brain structure leads them to postulate that reductions in gray matter volume in some cortical areas of the brain including hippocampus occur following gene-environmental interactions. Regarding prenatal complications, the list of risk factors continue to grow with effect size mentioned as an odds ratio of around 2.0 (Clarke et al. 2006).

The effects of both genes and environment on gene expression are called epigenetics. Environmental exposures, even stress and medication treatments, can affect gene expression. There may be critical periods in life when lifelong gene expression may be established such as during fetal life. The fetus receives signals about the health and environment of the mother through the placental circulation, including nutritional status, infection, and even stress. These exposures can determine the lifelong gene expression of the fetus through a process called fetal programming. The genotype of the individual may determine the developmental consequences of any fetal exposures or obstetric complications (Lieberman et al. 2006). However, according to Clarke et al. (2006), obstetric complications remain one of the best replicated “environmental” risk factors for schizophrenia but they are neither necessary nor sufficient causal factors for schizophrenia. Thus, further research in this area and with improved methodologies it is possible to have a stronger impact in decreasing the detrimental effects and interactions between genetic and environmental factors.

Pathophysiology

Whereas etiology refers to the cause of an illness, pathophysiology refers to the abnormal processes that mediate the clinical manifestation of the illness. As was the case with etiology, the brain processes that give rise to schizophrenia are currently not known. However, rapidly converging bodies of neuroanatomical and neurochemical data appear to be closing in on defining the pathophysiology of this illness. In this section, these data are reviewed.

Neuroanatomical Theories

The brains of patients with psychotic illnesses have been examined for hundreds of years. At the end of the 19th century, Alzheimer described loss of cortical neurons in patients with dementia praecox. In 1915 Southard noted cerebral atrophy in patients. Although these early reports were suggestive of a brain lesion in schizophrenia, only recently have the investigative tools become available to probe the human brain in enough detail to confirm cerebral abnormalities in this illness.

 Advances in in vivo brain imaging and postmortem methodology have provided powerful new tools for neuroanatomical investigations of this illness. In vivo structural brain analysis began in earnest with computed tomography (CT), which provided the most compelling evidence for morphological abnormalities in this illness. CT has been replaced by magnetic resonance imaging (MRI) for morphological studies because of its superior anatomical resolution (1 mm or less in-plane resolution), ability to provide true volumetric and three-dimensional analysis of even minute brain regions, tissue segmentation capability and because it involves no radiation exposure. Positron emission tomography (PET), single-photon emission computed tomography (SPECT), functional MRI (fMRI), and MR spectroscopy (MRS) are imaging tools used to assess the functional and neurochemical activity of specific brain regions. Magnetization transfer (MT) is a proton-weighted MRI image that can give information about the integrity of myelin. Diffusion Tensor Imaging (DTI) and Line Scan Diffusion Imaging (LSDI) are newer MRI approaches that can provide sophisticated information on the orientation and integrity of neuron fibers in vivo. DTI focuses on the diffusion of water in the brain and measures fractional anisotropy (FA) which measures the direction of flow or indirectly, lining up of neuronal fibers. Apparent diffusion coefficient (ADC) measures the water content, high or low. Advances in postmortem methodology include rapid access to brains after death, well-matched control groups, controls for antipsychotic exposure including studies of antipsychotic-naive populations, and application of new molecular biological techniques. The following
is an examination of the brain structures most often implicated in the pathophysiology of schizophrenia.

**Enlarged Ventricles**

The ventricles are the fluid-filled spaces in the center of the brain. The most consistent morphological finding in the literature of schizophrenia is enlarged ventricles which have been confirmed by a large number of CT and MRI studies (McCauley et al. 1999). The effect size of ventriculomegaly has been reported to be 0.7. Seventy-nine percent of the well designed studies report enlargement of lateral ventricles. CT studies have tended to use ventricle–brain ratios to assess lateral ventricular size, and MRI studies have used more sophisticated quantifications. Lawrie and Abukmeil (1998), in a review report approximately 40% difference in volume between schizophrenia patients and controls across all volumetric MRI studies. It should be noted that although the ventricular increases are statistically significant, the ventricles are not grossly enlarged in most cases. In fact, radiologists most often read CT and MRI scans of patients with schizophrenia as normal. In addition, most studies of ventricular size demonstrate overlap between patients and normal control subjects, indicating that many patients have ventricles in the normal range. Nonetheless, enlargement of the ventricles is the first consistently reported finding confirming a brain abnormality in schizophrenia. Chronically ill patients are reported to have substantially more ventricular enlargement compared to those who are in their first episode. Increase in ventricular size with the progression of illness has been reported too. In a 10-year longitudinal study of brain changes in schizophrenia, ventricular enlargement was progressive, and not a developmentally static finding (see Figures 65–3 and 65–4). In first episode subjects, a meta-analysis showed that lateral ventricles are significantly larger and the volume tends to increase significantly longitudinally (Steen et al. 2006). Many have speculated that these changes may begin early and can be detected even before the onset of psychosis. However, two studies of patients in their prodrome did not show ventricular enlargement or its progression (see DeLisi et al. 2006). Using DTI, when comparisons were done in high risk adolescents for schizophrenia and controls, there was already elevated CSF content in the left parahippocampal gyrus and right superior temporal gyrus in this group compared to controls. However, this was a small sample. Some studies have reported displacements in the left posterior horn compared to controls and also disproportionately enlarged temporal horn of the left lateral ventricle in schizophrenia; these changes are in important areas such as caudate nucleus, hippocampus, amygdala etc, raising important etiological questions.

The pathophysiological significance of larger than normal ventricles is unclear (Lawrie and Abukmeil 1998). There have been reports that enlarged ventricles may be more prominent in more severely ill patients and related to poor response to neuroleptic medication, although these findings have not been consistently replicated. Ventricular enlargement, particularly third ventricle and temporal horn enlargement, has been found in first-episode patients with schizophrenia, which suggests that it is not secondary to chronic neuroleptic exposure or a progressive disease process. However, frontal horn enlargement is usually seen in chronic cases, suggesting possible progressive changes following onset of the illness. Enlarged ventricles are most likely a secondary manifestation of brain atrophy or some other process resulting in either focal or generalized reductions in brain mass. Indeed, there have been many reports of brain atrophy and reduced mass in the illness (Figure 65–5). Enlarged ventricles have also been reported in first-degree

![Figure 65–3 Magnetic resonance imaging (MRI) of a female patient who initially was scanned at the time of hospitalization for a first episode of schizophrenia. At the tenth year of follow-up, at age 34, she was an outpatient with a diagnosis of chronic schizophrenia stabilized with predominantly negative symptoms.](image-url)

![Figure 65–4 Structural abnormalities in schizophrenia.](image-url)
relatives of subjects with schizophrenia and in persons suffering from schizotypal personality disorder raising interesting speculations of whether ventriculomegaly may be an indicator of neurodevelopmental risk for schizophrenia (Lencz et al. 2001).

Limbic System

The limbic structures that have been implicated in schizophrenia are the hippocampus, entorhinal cortex, anterior cingulate, and amygdala. These structures have important functions for memory (hippocampus), attention (anterior cingulate, and amygdala), and emotional expression and social affiliation (amygdala). The entorhinal cortex serves as a “way station” between hippocampus and neocortex in that neurotransmissions between these regions synapse in the entorhinal cortex. The entorhinal cortex, hippocampus, and other components of the parahippocampal gyrus are often considered “mesiotemporal” structures because of their close anatomical and functional relationship.

There are more reports of abnormalities in hippocampal and related mesiotemporal structures than other limbic structures in schizophrenia. In fact, mesiotemporal pathology is consistently found in studies of schizophrenia and mesiotemporal structures are leading candidates for the neuroanatomical site of this illness. This region has been implicated by converging brain imaging and postmortem lines of evidence. One of the most consistent MRI morphological findings is reduction in size of the hippocampus (Breier et al. 1992). In addition, more than 25 postmortem studies have reported morphological and cytoarchitectural abnormalities in this structure. The findings have included reduced size and cellular number, white matter reductions, and abnormal cell arrangement. Nelson and colleagues (1998), conclude from a meta-analysis of 18 studies that there is a bilateral reduction of approximately 4% hippocampal volume in schizophrenia. However, reduced hippocampal volume is not reported by all studies. In another review, Lawrie and Abukmeil (1998) reported approximately 6% reduction in amygdala hippocampal complex. Reduction in the volume of amygdala is reported by some but not all. In a very interesting preliminary report from Australia, subjects who went on to develop schizophrenia had larger left hippocampal volumes compared to controls at baseline (during the prodrome) with subsequent reduction in volume after the onset of schizophrenia. The same group recently published findings involving 473 subjects, measuring hippocampal and amygdala volumes in patients with chronic schizophrenia (n = 89), first episode schizophrenia (n = 162), and those with ultrahigh risk for psychosis (n = 135), and controls (87). Patients with chronic schizophrenia had bilaterally smaller hippocampi, first episode schizophrenia patients had reduced left sided hippocampal volume but not in patients with schizophrenia or other psychosis. Bilateral amygdala enlargement was present only in the first episode nonschizophrenia patients. The ultra high risk group (who did or did not develop psychosis) exhibited no hippocampal or amygdala volume changes compared to controls (Velakoulis et al. 2006).

The anterior cingulate has been implicated in schizophrenia largely because of postmortem findings of reduced gamma-amino butyric acid (GABA) interneurons. In addition, functional imaging studies have demonstrated altered metabolic activity both at rest and during selective attention tasks in the anterior cingulate in patients with schizophrenia. Data from many studies suggest possible neurodevelopmental abnormalities in anterior cingulate in patients with schizophrenia (Benes 2000). Bouras and colleagues (2001) reported mean total and laminar cortical thickness as well as mean pyramidal neuron size were significantly decreased in the dorsal and subgenual parts of anterior cingulate in patients with schizophrenia and auditory hallucinations. Similarly, Wernicke’s area, which is involved in the conception and organization of speech, has been hypothesized to mediate the thought disorder of schizophrenia, particularly conceptual disorganization. Support
for this hypothesis comes from a report of a patient with vascular and ischemic lesions of this region that produce Wernicke’s aphasia, a disruption in the organization of speech that resembles the thought disorder of schizophrenia. MRI studies have found a relationship between morphological abnormalities in this region and conceptual disorganization in schizophrenia (Shenton et al. 1992). McCarley and colleagues (1999) reviewed 118 MRI studies published from 1988 to 1998; 62% of the 37 studies of whole temporal lobe showed volume reduction and/or abnormal asymmetry. Of the 15 studies surveyed, 80% showed abnormalities in STG, the highest percentage of any cortical region of interest. This difference appears to be largely due to gray matter. Most studies, including those involving first episode patients, report abnormalities in planum temporale (area related to language) with specific reductions of left posterior STG gray matter. According to the authors, the higher percentage of abnormalities in specifically defined regions of interest of medial temporal lobe and STG suggests a nondiffuse distribution of temporal lobe structural changes. Reduced planum temporale volumes have been shown to be associated with positive symptoms. Narr et al. (2004) isolated regional volume deficits in patients experiencing their first episode of schizophrenia by using two novel and complimentary computerized surface-based image analysis techniques. Specifically, they compared hippocampal radial distances and perihippocampal cerebrospinal fluid distributions between diagnostic groups at thousands of homologous hippocampal surface locations allowing the identification of very large changes in hippocampal structure. They interpreted the results to suggest that volume reductions resulted from disturbed neurendevolvement rather than neurodegenerative processes. Patients without prior antipsychotic exposure had smaller hippocampal volumes compared with the healthy group.

When DTI studies were done in adolescents at high risk for schizophrenia, there were changes already taking place in the left STG suggesting that perhaps, the atrophic changes occur early. The authors postulate that these changes are occurring early in the areas involved in language processing (DeLisi et al. 2006). Progressive volume reductions of the left STG in first episode of schizophrenia patients but not in bipolar patients was reported after 18 months. STG volume reductions have been documented in nonpsychotic offsprings of patients with schizophrenia, suggesting that STG volume reductions may be a marker of risk for schizophrenia.

Prefrontal Cortex
The prefrontal cortex (PFC) is the most anterior portion of the neocortex, sitting behind the forehead. It has evolved through lower species to become one of the largest regions of the human brain, constituting approximately one-third of the cortex. It is responsible for some of the most sophisticated human functions. It contains a heteromodal association area that is responsible for integrating information from all other cortical areas as well as from several subcortical regions for the execution of purposeful behavior. Among its specific functions are working memory, which involves the temporary storage (seconds to minutes) of information, attention, and suppression of interference from internal and external sources. The most inferior portion of the PFC, termed the orbital frontal cortex (OFC), is involved in emotional expression. Given its unique role, it is not surprising that the PFC has been considered in the etiology of schizophrenia. Dorsolateral Prefrontal Cortex (DLPFC) is involved in working memory and other executive functions.

Indeed, several lines of evidence have implicated the PFC in schizophrenia. CT studies have provided evidence for prefrontal atrophy, and some, although not all, MRI studies have found evidence for decreased volume of this structure (Bremier et al. 1992, McCarley et al. 1999). One of the earliest observations from functional imaging studies of schizophrenia was reduced perfusion of the frontal lobes. This finding was subsequently replicated by several PET studies suggesting decreased frontal glucose utilization and blood flow, which came to be known as hypofrontality. Subsequent functional imaging studies provided further support for hypofrontality by demonstrating that patients with schizophrenia failed to activate their frontal lobes to the same degree as normal control subjects when performing frontal cognitive tasks. This finding has been questioned because patients with schizophrenia typically perform poorly in many cognitive paradigms, so it is unclear whether their lack of frontal activation is a primary frontal deficit or secondary to poor cognitive task performance related to factors such as lack of motivation, inattention, or cognitive impairment stemming from nonfrontal regions. Functional Neuroimaging studies used CPT and working memory tasks and repeatedly found reduced activation in DLPFC (Ford et al. 2004). Moreover, PFC dysfunction became especially pronounced when the task complexity increased requiring greater effort to perform relatively simple tasks. There was a corresponding greater activation of DLPFC such that with greater task complexity, schizophrenia patients start failing. Context dependent response selection and execution deficits have been associated with DLPFC activation deficits. PFC dysfunction appears to be wide spread and disturbed over the DLPFC, ventral and medial prefrontal regions, each contributing to specific aspects of the clinical and cognitive domains. fMRI studies in high-risk individuals for schizophrenia (prodromal) have reported significant deficits in the recruitment of PFC regions with further deterioration prospectively during the course of illness (Morey et al. 2005). Auditory hallucinations were found to be associated with increases in Broca’s area, a portion of the frontal cortex responsible for language production. This finding was of interest because it supported a hypothesis that auditory hallucinations were a form of abnormal “inner speech.”

MRI studies employing diffusion tensor imaging have reported changes suggestive of an abnormality in white matter connectivity possibly due to reduced myelination of fiber tracts in patients with schizophrenia. Magnetic resonance spectroscopy (MRS) studies have reported reduced levels of neuronal membrane constituents (phosphomonoesters) and/or increased levels of their breakdown products (phosphodiester) in patients with schizophrenia, primarily in the frontal cortex. Such abnormalities have been observed in treatment-naive first episode patients and have been correlated with trait-like negative symptoms and neurocognitive performance.

Though sometimes contradictory, the neuroimaging studies consistently report abnormalities in orbitofrontal region; often, these abnormalities tend to correlate with severity of schizophrenia symptomatology, show gender differences in relation to spatial localization and the gray matter
deficits may be more wide spread in chronic, as compared to medication-naive first episode patients (Lencz et al. 2001). Frontal lobe volumes were decreased in individuals with first episode of psychosis and showed progressive decline 30 months later. Increased cerebrospinal fluid volume in frontal lobes has been reported too. Additional support for PFC involvement in schizophrenia comes from postmortem studies with a range of findings. There have been reports of reduced cortical thickness, loss of pyramidal cells, malformed cellular architecture, loss of GABA interneurons, and evidence of failed neuronal migration. The Stanley Foundation Neuropathology Consortium is reported to be “the most extensively characterized collection of pathologi- cal specimens from patients with major mental illnesses.” Their exploratory analyses of PFC from patients suffering from schizophrenia, bipolar disorder, and depression compared with samples from normal controls found the largest number of abnormalities in schizophrenia with an overlap with bipolar disorder. A majority of the abnormalities represented a decline in function suggesting a widespread failure of gene expression. Specifically, abnormalities involving the glycoprotein Reelin were observed in schizophrenia, a finding reported previously by other postmortem studies also. Reelin, an extracellular matrix glycoprotein secreted from different GABAergic interneurons during development and adult life, may be important for the transcription of specific genes necessary for synaptic plasticity and morphological changes associated with learning. Reelin is believed to play a key role in directing cortical neuronal migration. Mutations in reelin can cause lissencephaly. Future studies will clarify the role of Reelin in the pathology of schizophrenia.

Thalamus
The thalamus is a nucleus that receives subcortical input and outputs it to the cortex. One theory posits that the thalamus provides a filtering function for sensory input to the cortex. A deficit in thalamic filtering was proposed to account in part for the experiential phenomena of being overwhelmed by sensory stimuli reported by many patients with schizophrenia. Preclinical studies have demonstrated that antipsychotic drugs modulate thalamic input to the cortex, which has been offered a model for antipsychotic drug action. Several MRI studies have reported reduced volume and functional abnormalities of thalamus in patients with schizophrenia. A metaanalysis of data from first episode psychosis patients suggests that there are volumetric changes in thalamus at baseline but may not be progressive unlike other regions of interest (Steen et al. 2006). Postmortem studies have also found cell loss and reductions in tissue volume in thalamic nuclei. This thalamic tissue reduction is considered as a possible evidence of abnormal circuitry linking the cortex, thalamus, and cerebellum.

Neural Circuits
Because of the large number of different neuroanatomical findings in studies of schizophrenia and the appreciation that brain function involves integration of several brain regions, current thinking about the neuroanatomy of this illness is centered on neural circuits. Thus, investigators are attempting to examine the integrity of a variety of cortical–cortical and cortical–subcortical neural networks that function together to execute behavioral programs. It is conceivable
that an isolated lesion anywhere in a neural circuit could result in dysfunction of the entire network, and therefore spurious conclusions could be drawn by investigating only one component of a neural network. Evidence suggests that schizophrenia may be associated with a decrease in synaptic connectivity of the dorsal PFC though this is not reported by all studies. McGlashan and Hoffman (2000) have proposed the Developmentally Reduced Synaptic Connectivity (DRSC) model which proposes that cortical gray matter deficits may arise from either reduced baseline synaptic density due to genetic and/or perinatal factors, or excessive pruning of synapses during adolescence and early adulthood or both. Margolis and colleagues (1994) propose that there could be graded apoptosis rather than a necrotic fulminating process. Apoptosis is a form of cell death that occurs in many neurodegenerative disorders in which intra- or extracellular physiologic events trigger a programmed sequence of cellular actions resulting in cell destruction and evacuation. According to Goldman-Rakic and Selemon (1997), there is regionally specific decreased neuronal size in cortical layer III with cytoplasmic atrophy and generally reduced neuropil. The reduced size and increased density of neurons or glia and decreased cortical thickness suggest that cell processes and synaptic connections are reduced in schizophrenia. This is consistent with reports of decreased concentrations of synaptic proteins (e.g., synaptophysin). This has been called “Reduced Neuropil Hypothesis.” (Glantz et al. 2006) (See Figure 65–6). These cell processes and synapses could be lost as a consequence of a neurochemically mediated (through dopamine and or glutamate) synaptic apoptosis that would compromise cell function and alter brain morphology without, however, producing serious cell injury (and thus inducing glial reactions). However, McCarley and colleagues (1999) suggest that the main neural abnormality in schizophrenia involves neural connectivity (dendrite/neuropil/gray matter changes) rather than the number of neurons or network size. They suggest that a “failure of inhibition” on the cellular level is present in schizophrenia and may be linked to a “failure of inhibition” at the cognitive level. According to Lafargue and Brasic (2000) abnormalities involving the temporolimbic–prefrontal cerebral circuitry are postulated to underlie the organizational and memory deficits commonly observed in schizophrenia patients. Furthermore, as reviewed by these authors, a possible insult or injury to the mechanism of GABAergic and glutamatergic influence during early corticogenesis may largely contribute to the later manifestation of clinical schizophrenia. Malfunction of the cooperating sensory systems of excitation and inhibition during the early stages of development of the brain could result in the failure of “pioneer neurons” to properly differentiate and migrate to their appropriate cerebral locations. Consequently the later migrating projection neurons may fail to reach or invade their preselected area-specific brain sites. A disturbance of the proper GABAergic and glutamatergic influences would upset NMDA mechanisms and normal cortical development. If such disturbance is actively occurring from the onset of cerebral ontogeny, the affected individual may suffer from the signs and symptoms observed in schizophrenia. A challenge for the future is developing new approaches to examining the brain as an integrated and highly interactive system. An unanswered question is whether the morphological differences reflect hypoplasia (failure to develop) or atrophy (shrinkage).

### Electrophysiology

Electroencephalogram (EEG) records the electrical activity of brain, which may reflect the mental functions carried out by the neurons possibly in “real time.” However, the precise localization of this event in the specific brain region is poor. Quantitive EEG (qEEG) involves computer assisted imaging and statistical analysis of the EEG for detecting abnormalities. A review of qEEG literature found that though 5–80% schizophrenia patients showed EEG abnormalities including increased slow activity in the delta and theta bands their significance is not clear. Clinically, individuals with schizophrenia often do not have EEG findings, and when they do, they are often of this nonspecific variety, unless there are other neurological disorders present.

When EEG activity from repeated presentations of a specific stimulus is summed across trials, some potentials...
related to the specific processing of the target stimulus can be extracted from the EEG and are referred to as event-related potentials (ERPs). The P300 ERP, a positive deflection occurring approximately 300 milliseconds after the introduction of a stimulus, is regarded as a putative biological marker of risk for schizophrenia. The P300 amplitudes are smaller in patients with schizophrenia and is one of the most replicated electrophysiological findings. The P300 ERP is often elicited with an oddball paradigm, wherein two stimuli are presented in a random series such that one of them occurs relatively infrequently and subjects are instructed to respond to the infrequent target stimulus. Though the exact neural locations of the normal P300 generation are uncertain, it is thought that discriminating the target from a standard stimulus should involve frontal lobe. If the neuroelectric events that underlie P300 generation are related to an interaction between frontal lobe and hippocampal/temporal–parietal function, disease states that affect frontal and temporal/parietal lobe function should also affect P300 measures. This hypothesis has been supported by findings of smaller P300 amplitudes over left temporal scalp locations relative to the homologous right temporal locations for patients with schizophrenia compared to controls. Remarkably, reductions in the left posterior superior temporal gyrus gray matter volume (using MRI) correlated with the reduction in the temporal P300 amplitude in chronic and first episode schizophrenia. Even though the magnitude of P300 component differences between patients with schizophrenia and controls is highly reliable across individual studies (Jeon and Polich 2001), variation for the group effect size is systematically associated with disease definition, stimulus parameters, task conditions, and recording methods.

N400 is a negative deflection in the ERP occurring approximately 400 milliseconds after introduction of a stimulus, whose latency is thought to reflect the speed of linguistic operations related to semantic search. Abnormalities in the N400 amplitude in schizophrenia have been reported. Investigators suggest that individuals with schizophrenia do not use the context of the preceding portion of the sentence and fill-in responses to phrases based on the immediately preceding word rather than the whole sentence or passage.

Investigations using newer probes such as atypical antipsychotic agents and their effects on ERPs are interesting; clozapine, in a small sample using a double blind paradigm, improved the amplitude of the P300 but chlorpromazine did not. Thus, future studies promise interesting information in this area.

**Sensory and Sensorimotor Gating**

An organism needs an internal mechanism to select from diverse sensory input the information that is necessary to function efficiently. This process is termed as sensory or sensorimotor gating. Thus, sensory gating refers to the basic ability of the brain to suppress the response to repeated and possibly irrelevant environmental stimuli. Measures of sensory or sensorimotor gating are among the most widely studied physiological markers used in laboratory studies of schizophrenia. P50 and Prepulse Inhibition are important paradigms developed to quantify sensory and sensorimotor gating respectively.

P50 is an early positive component of an auditory averaged Event Related brain Potential (ERP), which is recorded at the vertex 50 ms after a click stimulus. In the P50 paradigm, when two identical auditory stimuli (clicks) are presented in close temporal proximity to each other (usually 500 ms), the amplitude of the P50 ERP to the first auditory stimulus is larger than the second stimulus. This P50 amplitude reduction or suppression seen with the second stimulus is a measure of sensory gating. When subjects fail to show a diminished response to the second stimulus, this suggests a failure of inhibitory mechanisms apparently due to reduction in short-term habituation. Numerous studies have now confirmed that individuals with schizophrenia exhibit less P50 suppression than healthy controls.

In the Prepulse Inhibition (PPI) of startle paradigm, PPI is defined as an inhibition of the startle response when a low-intensity stimulus (a prepulse) precedes an acoustic startle stimulus. As the prepulse stimulus reduces the effect of the startle-eliciting stimulus, the percentage of PPI provides a measure of the amount of sensorimotor gating (as it involves both sensory stimuli and motor responses). Like P50 suppression, numerous studies have now reported reduction of PPI in individuals with schizophrenia compared to healthy controls.

Although both paradigms are thought to measure gating of incoming information, they are based on different physiological phenomena. P50 suppression is measured by EEG while PPI is measured by electromyography. In contrast to P50 suppression, PPI is not a form of habituation. Though available evidence suggests that PPI and P50 suppression are only weakly related in either healthy volunteers or in individuals with schizophrenia, they could involve common brain mechanisms that regulate cortical and brain stem responsivity. PPI is subserved by cortico-striato-pallido-thalamic circuitry that has interacting and overlapping neural substrates with P50 generation circuitry, especially in mesial temporal lobe structures. Evidence supports decreased sensory gating in schizophrenia due to disruption in architecture, function, and neurotransmitters of hippocampus. Because of this defect, the schizophrenic hippocampus and amygdala (that are responsible for development of emotional significance and response to environmental and internal contexts) are bombarded by a large amount of auditory sensory data that overwhelms the defective limbic system and causes psychiatric symptoms.

Most antipsychotic agents with the possible exception of clozapine do not normalize gating difficulties. However, nicotine improves the gating difficulties. Furthermore, a genetic linkage for the occurrence of sensory gating defect to the α7 nicotinic acetylcholine receptor gene on chromosome 15q–14 has been suggested. Thus, the P50 ERP has been viewed as a promising candidate endophenotype of schizophrenia, a genetically influenced biobehavioral characteristic that will enhance the likelihood of identifying schizophrenia susceptibility. The relationship between abnormal sensory gating and clinical symptoms of schizophrenia is not fully understood especially because the P50 deficit is still present in medicated schizophrenia patients. Moreover, these abnormalities are not restricted to schizophrenia but also occur in other psychiatric as well as neurological conditions. The cross-species nature of both P50 and PPI enables the use of animal models of induced deficits to study pathophysiology as well as develop targeted treatments of schizophrenia. Specifically, in this era of the MATRICS program (see...
Mismatch Negativity
Mismatch negativity is a particular component of ERP that has a negative peak at 100–200 ms, and is generated by a mismatch process between the sensory input from a deviant stimulus and a neural sensory-memory trace (echoic memory) storing the physical features of a standard stimuli. MMN is elicited by infrequent variations (called deviants) in frequently presented stimuli called standards and is considered to reflect automatic, preattentive brain processes. MMN, considered to be one of the most important phenomena in cognitive and clinical electrophysiology, is attenuated in schizophrenia. It was not reduced in first episode schizophrenia patients suggesting that reductions in MMN amplitude might develop over time and thereby index the progression of the disorder. Some suggest that MMN is an index of the functioning of an automatic alerting mechanism designed to stimulate individuals to explore unexpected environmental events. The exact physiological underpinnings of memory traces are still unclear; a popular candidate is the phenomenon of long-term potentiation (LTP) which is mediated at the molecular level mostly by NMDA receptors to glutamate. LTP occurs when presynaptic depolarization originating from the environmental input is tightly linked (synchronized) in time with postsynaptic depolarization which often originates from the previous experience as part of the learning mechanism. Thus, LTP specific postsynaptic depolarization reflects predictive brain activity, a sort of a standard generated by the brain with which to compare inputs. Unexpected inputs are not synchronized with postsynaptic activity pretuned for the expected stimuli. One hypothesis is that the resulting desynchronization at the synaptic level in a group of neurons can cause MMN.

A meta-analysis failed to find a clear association between negative symptoms and MMN reduction. However, recent data suggest that deficits in MMN are associated with poor functional status in schizophrenia patients indicating that MMN deficits represent a core neurophysiological dysfunction. Thus, it is not surprising that researchers are focusing on the possible relationships of deficits in MMN to deficits in higher cognitive functions. Salisbury et al. (2007) associated progressive reductions in MMN amplitude and reductions in left Heschl’s gyrus in a prospectively followed group of first episode schizophrenia patients providing support for involvement of auditory cortex in the pathogenesis of schizophrenia. However, simple volume loss does not account for the reduction in MMN. MMN reduction seems to stabilize following the first 1.5 years but that does not appear to be the case with the volumetric changes. Acute treatment with NMDA antagonists is also reported to lead to reduced MMN amplitude in both human as well as animal models leading to a possible explanation that alteration in subpopulation of cortical glutamatergic cells could trigger the sequences of events leading to reduced MMN generation.

Gamma Band Activity
Gamma band activity (GBA) is fast cortical oscillatory activity in the γ-frequency band (30–100 Hz) as recorded in humans using EEG or magnetoencephalography (MEG). GBA is of particular interest in neuroscience research as it has been linked to a variety of perceptual or selective attention. Intra-cortical recordings in animals indicate that neurons encoding the same sensory stimulus synchronize their firing activity to form a cell assembly that underlies the cortical representation of the relevant object. This synchronization gives rise to fast cortical oscillations with frequencies in the γ-band range. While broadly distributed activity in the lower γ range found in EEG may reflect synchronization between cortical areas involved in a particular type of processing, activity in the higher γ range identified in MEG appears to represent local network activation. From a physiological perspective, there are strong arguments for synchronization in the γ-frequency band being important for neuronal communication. The hypothesis that synchronous firings of a group of cells increase their functional impact has been the cornerstone of various theories of the role of oscillatory γ-frequency activity. It has been proposed that sustained neuronal firing in the γ-frequency is responsible for active maintenance of representations in working memory. A neuron receiving multiple synaptic inputs is more likely to fire if these inputs are synchronized. Synchronous firing has been reported to have stronger effect on receiving neurons in downstream areas. Attention relies on γ-band synchronization to integrate neural activities related to a specific sensory object into a stable, salient and coherent representation, which would then be available for further maintenance in short term memory or encoding into long-term memory. The synchronous assemblies mediating perception and the maintenance of memory do not necessarily belong to the same brain regions. Successful encoding and recall of long-term memory are associated with increased γ-frequency activity. During encoding, the increased γ-frequency activity provides a phasic drive to neurons that are already active. This might serve to entrain the γ activity in the receiving network and thus adjust the timing of neuronal firing to be optimal for synaptic plasticity. During recall, the increased γ-frequency activity might reflect reactivation of synthetically encoded representations. Thus, γ-band synchronization has been theorized to play a pivotal role in attention and memory with the suggestion that γ-frequency activity supports maintenance of working memory (Jensen et al. 2007).

Gamma-band responses of drug-free schizophrenia patients during an auditory oddball paradigm have identified a reduced evoked γ response in a late-latency range. Gamma oscillations with late onset are associated with perceptual and associative learning, object representation and selective attention. Additionally, altered γ-band synchronization in schizophrenic patients has been demonstrated using other sensory modalities. The interconnected, inhibitory GABA neurons are postulated to play an important role in the generation of the neuronal-network oscillations with possible dysfunction of parvo albumin-containing GABA neurons. Activation of the α7 nicotinic acetylcholine receptors, which are present predominantly on GABA interneurons in the hippocampus, may enhance ongoing oscillations that might contribute to pro-cognitive effects of agonists at these receptors. It is presumed that neuronal synchrony and net-work oscillations share many common processes in human and animals providing a unique opportunity to develop translational biomarkers for drug discovery using animal models.
Neurochemical Theories

Dopamine

Dopamine is the most extensively investigated neurotransmitter system in schizophrenia. In 1973 it was proposed that schizophrenia is related to hyperactivity of dopamine. This proposition became the dominant pathophysiological hypothesis for the next 15 years. Its strongest support came from the fact that all commercially available antipsychotic agents have antagonistic effects on the dopamine D₂ receptor in relation to their clinical potencies (Creese et al. 1975). In addition, dopamine agonists, such as amphetamine and methylphenidate, exacerbate psychotic symptoms in a subgroup of patients with schizophrenia (Lieberman et al. 1987). Moreover, as noted earlier, the most consistently reported postmortem finding in the literature of schizophrenia is elevated D₂ receptors in the striatum.

The dopamine hyperactivity hypothesis and the primacy of D₂ antagonism for antipsychotic drug action were seriously questioned largely because of the advent of clozapine, an atypical or second generation antipsychotic (SGA) drug. Clozapine has proved to be the most efficacious treatment for chronic schizophrenia and yet it has one of the lowest levels of D₂ occupancy of all antipsychotic drugs. In vivo brain imaging studies demonstrated that clozapine D₂ occupancy levels were as low as 20% more than 12 hours after the last dose of medication in patients deriving excellent antipsychotic efficacy (compared with more than 80% D₂ occupancy for haloperidol) (Farde et al. 1988) (Figure 65–7). This started an extensive search for explanations underlying the extraordinary efficacy of clozapine. However, new information from PET studies has once again highlighted the central role that the dopaminergic system plays in treatment of psychosis. The first generation antipsychotics (FGA) and the SGA are effective only when their D₂ receptor occupancy exceeds 50%–65%, reinforcing the importance of D₂ antagonism in producing antipsychotic effects. However, an important difference between the FGA and SGA is in the concomitant dopamine dysregulation causing dopamine increase in the striatum, perhaps related to faulty presynaptic control of dopamine release, and may be involved in positive symptoms. This bidirectional model is under investigation. Kapur (2003) proposed a link between dopamine hypothesis and clinical symptoms. He suggested that normally mesolimbic dopamine provides an external stimulus, or an internal thought with salience, which means that dopamine converts its mental representation from a neutral piece of information into one that ‘grabs the attention’ of the individual. During acute psychosis, where there is an

Figure 65–7 [¹¹C]Raclopride labeling of D₂ receptors in the striatum. (a) Medication-free healthy control subject. (b) Patient treated with 4 mg of haloperidol. (c) Patient treated with 500 mg of clozapine. (Source: Farde et al. (1988) Central D₂-dopamine receptor occupancy in schizophrenic patients treated with antipsychotic drugs. Arch Gen Psychiatr 45, 71–76. Copyright 1988 American Medical Association.) (See Color Plate XVI.)

was initially reported to have differential affinity for this receptor. Contrary to initial expectations, D₄ receptors do not uniquely distinguish SGA from FGA. Short-term clinical trials involving a limited range of doses of at least two drugs with high D₄ potency failed to show antipsychotic effects.

Clinical trials of dopamine agonists have resulted in improvements in the negative symptoms of schizophrenia. A revised model of dopamine dysfunction was proposed which stated that deficits in dopamine, perhaps in the prefrontal cortex, may result in negative and cognitive symptoms and that concomitant dopamine dysregulation causing dopamine increase in the striatum, perhaps related to faulty presynaptic control of dopamine release, and may be involved in positive symptoms. This bidirectional model is under investigation. Kapur (2003) proposed a link between dopamine hypothesis and clinical symptoms. He suggested that normally mesolimbic dopamine provides an external stimulus, or an internal thought with salience, which means that dopamine converts its mental representation from a neutral piece of information into one that ‘grabs the attention’ of the individual. During acute psychosis, where there is an
increased release of dopamine, salience is given (albeit inappropriately) to what would otherwise have been regarded as insignificant events and perceptions. This increased salience and overreaction to stimuli ultimately leads to paranoia and psychosis.

The DA hypothesis of schizophrenia has been critical in guiding schizophrenia research for several decades. Until recently, a main shortcoming of this hypothesis was absence of direct evidence linking DA dysfunction to schizophrenia. Sophisticated in vivo techniques have provided fascinating data directly implicating dopamine in developing psychosis. When the synthesis of dopamine in the brain was measured using PET scan following administration of radiolabeled fluro-L-DOPA, a dopamine precursor, an increase in dopamine was observed in drug-naive schizophrenia patients compared to age matched controls. Similarly, dopamine release in the basal ganglia was elevated in drug-naive schizophrenia patients compared to age matched controls when measured by PET and SPECT scans following an amphetamine challenge. This dopamine elevation correlated to the induction of positive symptoms of schizophrenia (Laruelle et al. 1996, Breier et al. 1997). Furthermore, SPECT studies using alpha-methyltyrosine showed that unchallenged release of dopamine was elevated in schizophrenia patients compared to controls (Laruelle et al. 1996). Arvid Carlsson, the Nobel Laureate, and his colleagues (Carlsson et al. 2001), whose work led to the original dopamine hypothesis, appreciate the significance of these data but observe that a wide scatter exists with some values of dopamine release being within normal range in patients with schizophrenia. They suggest that these findings may reflect heterogeneity where dopamine dysfunction may be limited to a subgroup of patients with schizophrenia. Furthermore, the observation that the elevated dopamine release correlates with a good clinical response to antipsychotic medications leads Carlsson and colleagues to suggest that DA release may be state dependent such that studies done in acute conditions may yield different results than in chronic remitted patient.

To complicate matters further, amisulpride and remoxipride, two benzamide compounds, which are highly selective for D2 and D1 receptors but are atypical, meaning they belong to the SGA category. Sulpiride, on the other hand, is a benzamide but belongs to the FGAs group. This raised the question of whether D2 receptors were heterogeneous. PET studies were able to confirm the heterogeneity of D2 receptors. When binding indices of select antipsychotics were determined in striatum and temporal cortex, there were markedly different profiles. These and other studies suggested that dopamine D2 receptor populations in striatum and temporal cortex were not identical. The speculation is that in striatum, the D2 population is dominated by synaptically located receptors whereas in temporal cortex the dominant receptor type is extrasynaptic. The dopamine D3 autoreceptor is also extrasynaptic but located on the dopamine neuron itself. Extrasynaptic receptors are thought to be more responsive than postsynaptic receptors. Carlsson and Carlsson (2006) have recently proposed hypotheses involving heterogeneity of dopamine receptors, and the notion that schizophrenia is related to a “dopaminergic deficit” wherein compensatory extrasynaptic transmission of dopamine occurs as a result of feedback activation, and this increased transmission is partly responsible for positive psychotic symptoms. The authors further postulate that the SGAs efficacy may lie in their ability to both bolster synaptic transmission of dopamine but limit extrasynaptic transmission via their partial D2 agonist properties. This hypothesis, though compelling, has yet to achieve widespread acceptance in the field. However, it has become increasingly clear that dopamine works closely with serotonin, glutamate, and other systems such that changes in one system affects the balance of the other systems too (see below).

Serotonin
Interest in serotonin as a pathophysiological candidate in schizophrenia arose in 1956 with the discovery that the hallucinogen lysergic acid diethylamide (LSD) had primary effects on serotonin neurotransmission. Several studies were conducted to characterize its behavioral profile to determine whether LSD psychosis was a suitable model of schizophrenia. Indeed, LSD produces some features of schizophrenia, including a profound psychotic state, distractibility, social withdrawal, referential thinking, and delusions. However, the most prominent feature of LSD psychosis is visual hallucinations, and auditory hallucinations are exceedingly rare. Visual hallucinations are quite rare among patients with schizophrenia and auditory hallucinations are among the most common symptoms of the illness. Thus, because of the failure to mimic key features of schizophrenia and the growing interest in dopamine at that time, enthusiasm for serotonin’s involvement in the pathophysiology of schizophrenia waned for some time.

Clozapine has a relatively high affinity for specific serotonin (5-hydroxytryptamine [5-HT]) receptors (5-HT2A and 5-HT2C) and risperidone, has even greater serotonin antagonistic properties. Most SGAs have a greater ratio of serotonin 5-HT2A to dopamine D2 binding affinity. This has led to the hypothesis that the balance between serotonin and dopamine may be altered in schizophrenia (Meltzer et al. 1989). Serotonin 5-HT2A (and other serotonin) receptor occupancy by the antipsychotic drugs, depending on the areas of the brain involved, along with the synergistic effect of Dopamine D2 and 5-HT2A antagonism could be associated with improvement in cognition, depression, and D2 receptor mediated EPS. This effect could be mediated by increase in prefrontal dopamine. Some have suggested that partial agonistic effects of some antipsychotics (e.g., aripiprazole, ziprasidone, etc) on 5-HT1A receptor may also increase prefrontal dopamine.

In addition to the renewed interest in serotonin because of the action of new antipsychotic drugs, several postmortem studies have found elevations of serotonin and its metabolites in the striatum of patients with schizophrenia. Again, as was the case with striatal D2 receptors, previous antipsychotic exposure may have contributed to this finding. Another common finding is decreased 5-HT2A receptor densities in prefrontal cortex. Several postmortem studies and an in vivo PET study have shown elevation of 5-HT1A receptor density in the cortex of patients with schizophrenia. The relevance of these findings are not clear. Some, but not all investigators, have reported that the partial serotonin agonist m-chlorophenylpiperazine causes psychotic exacerbations in patients with schizophrenia but has no psychosis-inducing properties in normal control subjects.
There has been an explosion of new information about the structure and function of 5-HT receptors with identification of numerous serotonin receptor subtypes. 5-HT_{1A}, 5-HT_{2A}, 5-HT_{3}, and 5-HT_{4} have been proposed as candidates for atypical drug action and are therefore reasonable targets for pathophysiological studies of schizophrenia. It is clear that the field is in the early stages of understanding the possible involvement of serotonin in schizophrenia.

Glutamate and N-Methyl-D-aspartate Receptor
Glutamate is the primary brain excitatory amino acid neurotransmitter and is critically involved in learning, memory, and brain development. Approximately 60% of the neurons in the brain including all cortical pyramidal neurons and thalamic relay neurons use glutamate as their primary neurotransmitter. The glutamate receptors are divided into ionotropic and metabotropic receptors. The Ionotropic receptors are linked directly to ion channels and include N-methyl-D-aspartate (NMDA), AMPA, and kainate; metabotropic receptors are linked to second messenger systems and are divided into group I, II and III according to their functional activity. Interest in glutamate and the NMDA receptor in schizophrenia arose because of the similarity between phencyclidine (PCP) psychosis and the psychosis of schizophrenia (Javitt and Zukin 1991). PCP is a noncompetitive antagonist of the NMDA receptor and produces a psychotic state that includes conceptual disorganization, auditory hallucinations, delusions, and negative symptoms. PCP produces more symptoms that are similar to those of schizophrenia than most other pharmacological agents. It should be noted that PCP produces behaviors that are not commonly seen in schizophrenia as well, including spatial and temporal distortion, dreamlike states, and violence. Other findings that support a hypoglutamatergic function in schizophrenia are decreased glutamate levels in cerebrospinal fluid and increased NMDA receptor number and decreased glutamate binding in neocortex in postmortem studies. Olney and Farber (1995) further refined the “NMDA receptor hypofunction” hypothesis by demonstrating that glutamate, acting through NMDA receptors on GABAergic neurons, maintains tonic inhibitory control on numerous excitatory pathways including regulation of its own firing rates such that NMDA receptor hypofunction would abolish this inhibitory control resulting in chaotic, heightened discharges which may account for psychological dysfunction and eventual degeneration of these affected neurons observed in schizophrenia.

PCP and other highly potent NMDA receptor antagonists, such as MK-801, cause neuronal damage and therefore are not used as research tools in clinical populations. However, ketamine, a widely used dissociative anesthetic, is another noncompetitive NMDA antagonist and, at subanesthetic doses, produces a PCP-like psychosis resembling schizophrenia. In a PET study of healthy volunteers, subanesthetic ketamine administration produced a robust psychotic state and focal activation of the prefrontal cortex, suggesting that prefrontal NMDA receptors may mediate this schizophrenia-like behavioral syndrome. The Glutamate hypothesis of schizophrenia is one of the most active areas of research currently. Postmortem studies have reported alterations in NMDA receptor expression in certain brain areas of patients with schizophrenia (Gao et al. 2000). NMDA receptor is reported to play a critical role in guiding axons to their final destination during neurodevelopment. Also, abnormalities with glutamate transmission are reported in many areas of the brain such as frontal cortex, hippocampus, limbic cortex, striatum, and thalamus. Moreover, there are changes reported in the gene expression also in these areas. Some of the risk genes identified for schizophrenia also affect glutamatergic system. In animal models of NMDA receptor antagonists, SGA agents are more effective in ameliorating symptoms (Gainetdinov et al. 2001). Thus, hypoglutamatergia in schizophrenia may have very important downstream modulatory effects on catecholaminergic neurotransmission and play a critical role during neurodevelopment. It also plays an important role in synaptic pruning and underlies important aspects of neurocognition.

GABA
GABA is the major inhibitory neurotransmitter in brain. Support for GABA’s involvement in schizophrenia comes from two lines of investigation. First, clinical trials have demonstrated that benzodiazepines, administered both in conjunction with antipsychotic drugs and as the sole treatment, are effective at reducing symptoms in subgroups of schizophrenia patients. Benzodiazepines are agonists at GABA_{A} receptors. Second, postmortem studies have consistently report reduced levels of the mRNA for the 67-kilodalton isoform of glutamic acid decarboxylase (GAD_{67} encoded by GAD1), a major determinant of GABA levels in the DLPFC of schizophrenia subjects. Additional findings suggest that both the synthesis and the reuptake of GABA are reduced in a subset of DLPFC neurons in schizophrenia. The affected GABA neurons are the parvalbumin positive chandelier neurons whose axons synapse exclusively on the axons of pyramidal neurons. This results in decreased GABA synthesis and release, and induces compensatory response including decreased presynaptic GABA reuptake and upregulation of postsynaptic GABA_{A} receptors. Reduced GABA signaling from chandelier cells to pyramidal neurons could contribute to the pathophysiology of working memory dysfunction (see Lewis and Gonzalez-Burgos 2006 for more details). A deficit in GABA interneurons in the anterior cingulum and prefrontal cortex and hippocampus of schizophrenia patients raise interesting possibilities underlying the etiology of schizophrenia (see Figure 65–7a). These interneurons are under control of neuronal patterning and associated genes and thus may represent a genetic vulnerability possibly contributing to the decreased regional brain size. Moreover, deficiency in GABA signaling may allow excitatory system to be overactive and resultant downstream effects. Also, GABAergic neurons are especially vulnerable to glucocorticoid hormones and also to glutamatergic excitotoxicity.

Peptides
Several peptides have been hypothesized to play a pathophysiological role in schizophrenia. Interest in neurotensin arose because of the discovery that it is colocalized in some dopaminergic neurons and acts as a neuromodulator of this and other neurotransmitters. In preclinical studies, neurotensin was found to have effects that resembled those of antipsychotic drugs and antipsychotic drugs cause increases in neurotensin levels in rat brain. In addition, schizophrenia patients were found to have lower cerebrospinal
fluid neurotensin levels than healthy control subjects and other patients with neuropsychiatric disorders. It has been suggested as a novel target for treatment of psychosis (Caceda et al. 2006). Another peptide with neuromodulatory actions that was found to be colocalized with dopamine and was therefore of interest in relation to schizophrenia is cholecystokinin. Unlike the case of neurotensin, however, there has been a lack of consistent data from postmortem and cerebrospinal fluid studies of patients with schizophrenia. Moreover, a clinical trial of CCK-8, a cholecystokinin analogue, has failed to demonstrate antipsychotic efficacy. Other peptides that are under consideration for a pathophysiological role in schizophrenia are somatostatin, dynorphin, substance P, and neuropeptide Y.

Norepinephrine
Heightened noradrenergic function has been implicated in psychotic relapse in subgroups of schizophrenia patients. In addition, clozapine, but not other antipsychotic drugs, consistently produces increases in central and peripheral indices of noradrenergic function, and one study found a significant relationship between increases in plasma norepinephrine and improvement in positive symptoms (Breier et al. 1994) (Figure 65–8).

The Dopamine–Glutamate Theory
Carlsson and colleagues (2001) provide a multineurotransmitter theory of schizophrenia which improves upon previous biochemical theories of schizophrenia. Accumulating evidence suggests that hyperdopaminergia in schizophrenia is probably secondary to some other phenomena. The data involving glutamatergic system suggest that NMDA receptor antagonism enhances the spontaneous and amphetamine-induced release of dopamine and thus raises the possibility that hypoglutamatergia could be related to the hyperdopaminergia. Carlsson and colleagues (2001)
propose that psychotogenensis depends on an interaction between dopaminergic and glutamatergic pathways projecting to the striatum from the lower brain stem and cortex, respectively. These neurotransmitters are predominantly antagonistic to each other, the former being inhibitory and the latter stimulatory when acting on striatal GABAergic projection neurons. These GABAergic neurons belong to striatofugal pathways, which exert an inhibitory action on thalamocortical glutamatergic neurons, thereby filtering off part of the sensory input to the thalamus to protect the cortex from a sensory overload and hyperarousal. Hyperactivity of dopamine or hypofunction of the corticostriatal glutamate pathway should reduce this protective influence and could thus lead to confusion or psychosis. As a result, the indirect striatothalamic pathways have an inhibitory influence on the thalamus with the corresponding direct pathways exerting an opposite and excitatory influence. Both pathways are controlled by glutamatergic corticostriatal pathways enabling the cortex to regulate the thalamic gating in opposite directions. Thus, according to Carlsson and colleagues (2001), they appear to serve as brakes and accelerators.

It has been suggested that the activity of the direct pathways is predominantly phasic and of the indirect pathways is mainly tonic. This difference could have important consequences for a different responsiveness of the direct and indirect pathways to drugs. Thus the NMDA receptor antagonists are behavioral stimulants. AMPA receptor antagonists act in the same direction as NMDA antagonists in some and opposite direction in other experiments. Thus, the two most important animal models of psychosis are those induced by hyperfunction of dopamine and hypofunction of glutamate. The relationship between glutamate and serotonin is very important and interesting. Serotonin appears to play a more important role than dopamine in the behavioral stimulation induced by hypoglutaamatergia. In two models of psychosis, haloperidol is quite powerful in alleviating the hyperdopaminergic stimulation induced by amphetamine but is less efficacious in the hypoglutaamatergic behavioral stimulation induced by MK-801. However, M100907, a selective serotonin 5-HT1A antagonist is clearly more powerful in counteracting MK-801 than amphetamine-induced stimulation. These observations indicate that serotonin may play a more prominent role than dopamine in the behavioral stimulation induced by hypoglutaamatergia. Schizophrenia is a syndrome of heterogeneous etiology and pathology. If one neurotransmitter is disturbed, it will inevitably have an impact on other neurotransmitters (Carlsson et al. 2001).

**Neurodevelopmental and Neurodegenerative Disease Processes and Neuroprotection**

Neurodevelopmental hypotheses of schizophrenia posit that a disruption in normal development causes the illness (Cannon et al. 2000). Thus, the “lesion” occurs well before the onset of the illness and interacts with maturation events such as neuronal precursor; glial proliferation and migration; axonal and dendritic proliferation; myelination of axons; programmed cell death and synaptic pruning (Lieberman 1999a); and is in all likelihood a nonprogressive disease process. Support for the neurodevelopment hypothesis includes the fact that brain morphological abnormalities commonly found in this illness, such as enlarged ventricles and reduced mesolimbic structures, are present at the onset of the illness. Moreover, gliosis, which occurs during active pathological processes as part of the cellular reparative process in mature brains, is not commonly found in postmortem studies of schizophrenia.

That illness onset typically occurs in the teenage years and early twenties, as opposed to earlier in life when the proposed pathogenic insult occurs, has been explained by the fact that neural circuits implicated in this illness, are still undergoing myelination as well as synaptic “pruning” during the adolescent years and are therefore not fully functional until that time. Thus, an early lesion involving this region could remain silent until adolescence, when its normal functional capacity is expected to be realized. However, these assumptions have been questioned based on the MRI findings of changes in the volume of brain areas in patients with schizophrenia over a period of time (Lieberman 1999b, Weinberger and McClure 2002). This has generated interest in the “neurodegenerative hypothesis” of schizophrenia as originally proposed by Kraepelin and others. However, Weinberger and McClure have cautioned against interpretation of the MRI data without converging information from other areas.

More recent evidence supports both a degeneration process as well as developmental process. Thus, these are not mutually exclusive hypotheses, although they may be dominant at different stages of illness and have separate risk factors. Neurodevelopmental and neurodegenerative models could be conceptualized in one model. An individual’s vulnerability genes may influence the development of a prodromal condition. Other exposures such as stress, substance abuse etc may further trigger the onset of psychosis, which may lead to deterioration. Psychosis may represent a tip of the iceberg of an underlying pathogenic process that is damaging the brain. However, psychosis may need to be treated promptly to prevent degeneration and/or deterioration. Prolonged psychosis or even residual positive symptoms may well create deficits that add to the severity beyond the level ultimately determined by the original brain pathophysiology. Whether these further deficits result from brain-damaging neurotoxicity or from attenuated synaptic plasticity secondary to withdrawal from daily routine, it is significantly related to a deteriorating course even when patients are on stable medications (Lieberman et al. 2006, McGlashan 2006).

Neuroprotection refers to an intervention that helps to maintain the functional integrity of the central nervous system. Progressive brain changes accompany the functional decline early in the course of illness. Neuroprotection strategies are potentially useful both as therapeutic interventions to improve actual loss of function, and as a prophylactic intervention to minimize anticipated loss of function. Functional deterioration follows the formal onset of psychosis in most patients. Patients with prodromal symptoms who were at high risk for conversion to psychosis were scanned by MRI at study entry and prospectively. Only those patients who actually went on to become psychotic demonstrated a significant loss of cortical gray matter in specific regions of the cortex such as orbito-frontal, medial and inferior temporal lobe, cingulate gyri, and the cerebellar cortex. Progressive brain changes were observed even at the very earliest stages of schizophrenia. Similarly, in patients with childhood-onset schizophrenia, regionally specific progressive loss of cortical
gray matter especially in the prefrontal cortex, the parietal cortex and the temporal lobe has been reported. The annual rate of loss varied between 1 and 4% of cortical gray matter in these regions. These studies suggest that there was progressive loss of gray matter in early stages of the illness. Similar changes have been reported in first episode schizophrenia patients too. Thus, these observations have led to a hopeful conclusion that if the rate of progressive decline can be slowed both in gray matter loss and in overall level of function, then patients can have better long-term outcomes.

Amongst several underlying mechanisms, glutamate excitotoxicity appears more plausible. Hypofunction of the N-methyl-D-aspartate (NMDA) glutamatergic receptor may paradoxically lead to glutamatergic disinhibition associated with excess release of glutamate, resulting in excitotoxicity. This may account for both the clinical symptoms as well as the neuropathological deficits. While it has been difficult to demonstrate evidence of glutamatergic excitotoxicity, in patients with schizophrenia, significant reduction in the density of dendritic spines on pyramidal neurons in prefrontal cortex has been reported. This reduction of synaptic content, or neuropil, is consistent with the loss of cortical gray matter observed in neuroimaging studies. In a 2-year double blind randomized study, Lieberman and colleagues (2005) compared haloperidol and olanzapine in first episode psychosis patients. Almost 300 subjects participated. Olanzapine treated patients showed no significant change in whole brain gray volume over the course of the 2-year study. In comparison, the haloperidol patients showed a significant loss in whole brain gray volume starting at 12-week mark and continuing over the course of the 2-year period with significance being lost only at 2-year mark, likely because of considerable patient attrition by that time. This is the first randomized study demonstrating that the choice of antipsychotic treatment could affect progressive loss of gray matter occurs in first-episode psychosis. The total volume of gray matter is about 700 cc’s and the average loss was 10–12 cc’s. This may have a significant impact on cognitive and functional recovery. Neurocognitive composite scores indicated that for haloperidol-treated patients, less improvement in neurocognitive function was associated with greater rate of loss was between 1 and 4% of cortical gray matter in these regions. These studies suggest that there was progressive loss of gray matter in early stages of the illness. Similar changes have been reported in first episode schizophrenia patients too. Thus, these observations have led to a hopeful conclusion that if the rate of progressive decline can be slowed both in gray matter loss and in overall level of function, then patients can have better long-term outcomes.

Positive and Negative Symptoms

There has been an emphasis on positive and negative symptom clusters in some schizophrenia patients. Positive and negative symptoms were first described by Sir John Russell Reynolds, a British neurologist who had worked with epileptic patients. In 1857, in a presentation to a division of the London Medical Society, he proposed that physical signs could manifest themselves in positive and negative forms. The prominent neurologist Hughlings Jackson expanded on Reynolds’ statement by positing that negative symptoms could be thought of in terms of an upper motor neuron deficit that leads to the lower motor neuron hyperactivity, which he identified as a positive symptom. By definition, then, both negative and positive symptoms would be found in the same individual and there would be a causative relationship between them. In the psychiatric literature, positive symptoms have come to mean those that are actively expressed, such as hallucinations, thought disorder, delusions, and bizarre behavior, whereas negative symptoms reflect deficit states such as avolition, flattened affect, and aloia.

How these distinct symptom patterns are related in schizophrenia remains unresolved. Bleuler had conceptualized fundamental and accessory symptoms, and Schneider had divided symptoms into those of first and second rank, but neither specifically addressed positive and negative symptom subdivisions. Strauss and colleagues considered positive and negative symptoms as distinct symptom patterns associated with clinical course over time, with negative symptoms being more associated with poor long-term outcome. Subsequent hypotheses considered positive and negative symptoms to be either two end points of a spectrum of symptoms or a single disease process in which either the positive or negative symptoms are primary and the other symptoms become a secondary response.

Crow (1980) suggested that schizophrenia could be divided into a two-syndrome concept. According to his theory, type I schizophrenia patients are those who present, often more acutely, with a predominantly positive symptom profile and who have a good response to neuroleptics. In contrast, type II schizophrenia patients are those who have a more chronic illness, more frequent evidence of intellectual impairment and enlarged ventricular size and cortical atrophy as seen on CT or MRI scans, a poorer response to neuroleptics, and predominantly negative symptoms. Crow further postulated that type I schizophrenia may be secondary to a hyperdopaminergic state, whereas type II disease may be due to structural abnormality of the brain.

The idea that positive and negative symptoms may be overlapping end points along a single continuum of biological and clinical manifestations has been described by Andreasen and colleagues (1982). In their study of 52 schizophrenia patients, they found that negative symptoms correlated with the presence of ventricular enlargement and that patients with small ventricles were more likely to manifest positive symptoms. Furthermore, their group posited that negative and positive symptoms reflect opposite extremes of a spectrum and that a mixed symptom pattern can exist and may be present 30% of the time. Others have suggested that although the positive and negative characteristics may be part of a continuum, they may not be related to the presence or absence of structural brain abnormalities; rather,
there may be a relationship between the symptom pattern and outcome, depending on the clinical course. A categorical scheme for differentiation of so-called primary and secondary negative symptoms was developed by Carpenter and colleagues (1985). This distinction is based on the fact that negative symptoms are not pathognomonic of schizophrenia. The negative symptoms that can be seen in a number of other illnesses, including depression and medical illness, and as a result of positive symptoms themselves or the side effects of medication, particularly extrapyramidal symptoms, are considered “secondary.” The negative symptoms that are a core element of schizophrenia are deemed “primary” or “deficit” symptoms. This distinction enables further exploration of outcome variables and the heterogeneity of this illness and in many ways aids treatment decisions.

Because positive and negative symptoms may be seen differently by individual psychiatrists, valid psychometric scales have become important clinical and research tools. The Brief Psychiatric Rating Scale (BPRS), for example, includes subscales for positive and negative symptoms, as does the Positive and Negative Syndrome Scale (PANSS) for schizophrenia. Others have more broadly defined negative symptoms. Crow proposed the use of a narrow definition, that is, flattened affect and poverty of speech, for negative symptoms, and Andreasen supported a broader definition in the widely used Scale for the Assessment of Negative Symptoms (SANS). This psychometric scale includes categories of alogia and flattened affect as well as items such as anhedonia, asociality, avolition, apathy, and deficits in attention.

Structured Clinical Interview for DSM-IV (SCID) is a semi-structured diagnostic interview designed to be administered by an experienced clinician. Though primarily used in research, a user-friendly clinician version (SCID-CV) is also available. It is a very helpful instrument for systematic evaluation in psychiatric patients.

Symptom Cluster Analysis

Although the dichotomous positive–negative distinction has received clinical and research recognition, several reports suggest that this division is incomplete. Much of the interest in understanding the heterogeneity of schizophrenia has involved a more detailed look at the symptoms of schizophrenia. Sophisticated statistical techniques utilize factor analysis to reduce data to elucidate clusters of symptoms that are most likely to group together or be found independently.

An application of this approach found that there are three, rather than two, symptom dimensions that better subdivide schizophrenia. Correlational relationships between symptoms reveal that positive symptoms can be divided into two distinct groups. The first includes psychotic symptoms such as hallucinations and delusions, and the second includes symptoms of disorganization, consisting of thought disorder, bizarre behavior, and inappropriate affect. A third group is that of negative symptoms. Although these patterns of symptoms may be seen in different proportions in individuals and may change over time, they can be shown to have distinct clinical courses and may be related to independent neuropsychological deficits in a given individual.

In a 2-year follow-up study of these different symptom patterns, negative symptoms were found to remain stable and the other two dimensions were found to have a more fluctuating pattern. This study found that the three symptom dimensions changed independently.

An earlier report supporting three distinct symptom dimensions came from a study of neuropsychological and neurological findings in relation to schizophrenic symptoms. In this study, patients with a predominantly negative symptom dimension were shown to have cognitive deficits related to the frontal lobe, as were patients with thought disorder and inappropriate affect, but the specific deficits appeared to be related to different regions of the frontal lobe. Furthermore, patients who presented primarily with delusions and hallucinations appeared to have neuropsychological deficits associated with the temporal lobe.

Further investigation is warranted to understand the role of these three symptom dimensions in the onset, course, and treatment of schizophrenia. In addition, this factor analytical division of schizophrenic symptoms must be evaluated to understand their relationship to genetic and neurochemical mechanisms.

Cognitive Impairment

In an attempt to describe schizophrenia in a way that was different from prevailing psychodynamic principles of the day, McGhie and Chapman (1961) reported that schizophrenia patients demonstrated profound deficits in selective attention. This idea had also been described earlier by both Kraepelin and Bleuler. At present, there is a growing body of literature supporting this observation. By now it is widely accepted that schizophrenia patients experience neuropsychological deficits that can be characterized by difficulties with working memory, attention/vigilance, information processing, executive function, verbal learning and memory, visual learning and memory, reasoning and problem solving, speed of processing and social cognition which leads to a generalized performance deficit. Typically, there is a wide variance with some aspects of performance being more impaired than others. Interestingly, small subgroups of the patients have cognitive functioning within the normal range. Most patients with schizophrenia have only modest reductions in their IQs with an average of 90, and about 0.67 standard deviation below that of the general population. In contrast, their performance is usually worse even in first episode patients. Usually patients with schizophrenia underperform relative to estimates of their premorbid functioning (Harvey 2001). Cognitive impairments involving verbal learning, verbal delayed recall, working memory, vigilance and executive functioning have a significant negative impact on social and occupational functioning. Two meta-analysis of 24 and 9 studies respectively suggest that treatment with SGA agents improve cognitive function compared to FGA (Keefe et al. 1999, Harvey 2001).

The degree-of-cognitive deficit appears to be more strongly associated with severity of negative symptoms, symptoms of disorganization, and adaptive dysfunction than with positive symptoms. Verbal fluency is severely impaired in patients with psychotic disorders and the use of SGA result in significant improvement (Keefe et al. 1999). Motor functions (e.g., reaction time, motor and graphomotor speed) improve with clozapine, olanzapine, and risperidone. Olanzapine improves motor functions more than either haloperidol or risperidone. Furthermore,
motor functions are related to outcome, underscoring the importance of this domain. The symbol-digit and digit-symbol tests have been among the most responsive tests to SGA treatment (Keefe et al. 1999).

As a test of executive function, performance on the Wisconsin Card Sorting Test (WCST) improves with clozapine, risperidone, and olanzapine, although many negative findings have been reported. In Wisconsin Card Sorting Test, subjects sort a series of stimulus cards by matching them to four “key cards” that differ by form, color, and number. Successful performance on the WCST depends upon learning how to sort the cards and how to switch the sorting strategy when appropriate, since the “correct” sorting strategy changes after 10 consecutive correct responses.

Though the SGAs appear to have beneficial effects on cognition, much work still remains to eliminate biases; also, effect sizes of these improvements are modest (Harvey and Keefe 2001).

Information Processing, Vigilance and Attention
The term information processing is used to describe the process of taking information and encoding it in such a way that it can be understood and recalled when appropriately cued. This construct is related to neural circuits and a stepwise logical spread of neurochemical messages, which may be impaired in schizophrenia. Attention, simply defined, is the ability to focus on a stimulus, either through conscious effort or passively. These two constructs are interrelated, and our understanding of their composite parts has increased in complexity in the past few decades. Vigilance refers to the ability to maintain attention over time.

Measures of attention were developed from the idea that patients with schizophrenia cannot block out unimportant stimuli in the way that those without schizophrenia can. This phenomenon has come to be called gating. Gating is usually seen, for example, when a weak stimulus is delivered before a real stimulus. Normally, the first stimulus would dampen or eliminate the response to the second. Two measures to assess gating function in patients with schizophrenia are the P50 event-related potential (related to sensory gating) and prepulse inhibition of the startle response (related to sensorimotor gating). As an example of these measures, the P50 event-related potential examines responses to auditory stimuli, and the amplitude and the P50 is indicative of a response change between two stimuli. The amplitude reduction of the P50 response from a first auditory click to a second auditory click is known as P50 suppression. Data suggest that patients with schizophrenia have significantly lower than normal levels of P50 suppression.

Specific methods employed in the assessment of information processing and attention are numerous and has been reviewed. The general principles behind each technique are related. Continuous performance tasks, for example, are tests of attention in which the subject must isolate a specific stimulus among repeated distracter stimuli. The stimulus can be in any sensory modality, such as a tone or a letter flashed on a screen. Another test of information processing is prepulse inhibition, which is the inhibition of a startle response by a weaker warning stimulus. Event-related potentials measure electrical brain activity after some sort of stimulus such as an auditory click.

Other information-processing measurements reported to be abnormal in some schizophrenia patients included the skin conductance orienting response. This test involves habituation to a stimulus applied to the skin. Eye-tracking abnormalities such as smooth pursuit eye movements have also been found to be abnormal in schizophrenia patients.

In general, patients with schizophrenia have impairments in information processing, especially when they are exposed to increasing demands on their attentional capabilities, such as under timed conditions or in stressful situations. Therefore, these deficits not only are viewed as trait linked (i.e., a manifestation of the illness itself) but may be compounded when state linked (i.e., when there are increases in symptoms). The trait-linked disturbances in neuropsychological parameters are seen in those at high risk for developing schizophrenia, those who have schizophrenia, and relatives who appear clinically unaffected, which may indicate a genetic vulnerability.

Many of these tests of attention and information processing have been associated with specific symptoms and neuropsychological impairment in schizophrenia. For example, one study showed that impaired prepulse inhibition was related to increased perseveration on neuropsychological tests of higher executive function. Others have shown that deficits in attention and information processing may be associated with positive and/or negative symptoms. Specifically, deficits in visual processing and motor function (as seen with continuous performance tasks) have been linked to negative symptoms, whereas positive symptoms seem to be related to auditory-processing dysfunction. Deficits in vigilance can affect social interactions, community functions and acquisition of skills (Green 2006). Interestingly, abnormalities in these tests of information processing are not induced by FGAs; moreover, these medications may partially ameliorate the deficits. Attention has been reported to improve with SGAs. Because these deficits are seen more frequently in individuals with schizophrenia, their relatives, and those at risk of developing schizophrenia, the application of information-processing and sophisticated attention techniques may lead to more information about the heritability and genetics of schizophrenia. Further investigation regarding their correlation with specific symptom clusters, the effects of antipsychotic medications, and the relationship of these deficits to specific brain regions studied with PET and functional MRI should enhance our understanding of the neurocircuitry involved in these impairments.

Learning and Memory
Although there are generally no consistent gross deficits of memory in schizophrenia patients, close examination of certain aspects of learning and memory has revealed striking abnormalities. Schizophrenia patients have been shown to be poorer in recall of word lists if the words are not grouped into categories. Furthermore, unlike normal control subjects, schizophrenia patients do not seem to show an improvement in memory when asked to recall words with latent positive emotional meaning. These findings have been attributed to poor cognitive organization in schizophrenia patients.

Others have reported that patients with chronic schizophrenia had impairment in new learning and short-term memory but not remote memory, possibly indicating temporal–hippocampal dysfunction. These may be more
likely in patients with a poor premorbid course and ventricular enlargement. In addition, in a long-term follow-up study of schizophrenia patients, those with memory impairment had a poorer outcome in terms of social and occupational function.

FGAs have not been shown to affect memory, unlike anticholinergic medications, which may decrease memory performance (Chakos et al. 2006). Despite these findings, some questions regarding the role of chronicity and FGA exposure in memory impairment has remained. It appears, however, that these deficits are inherent to schizophrenia itself, as impairment in verbal memory has been demonstrated even in antipsychotic-naive first-episode schizophrenia patients. Data from nine small sample studies did not suggest that SGAs significantly improved verbal memory. However, two recent small studies suggest that quetiapine may improve verbal memory.

Working memory is a cognitive system that stores and processes information needed for planning and reasoning for a brief duration. Some cognitive scientists refer to short-term memory as working memory. Working memory consists of verbal and visual memory subsystems with a central principle that manipulates and coordinates information stored in the two systems for problem solving, planning and organizing activities. Separate areas of the prefrontal cortex may underlie different aspects of the working memory. The workspace used for such memory is capacity-limited. Patients with schizophrenia have significant dysfunction in this area and are unable to change an ineffective strategy (i.e., shift sets) even when feedback is provided. This dysfunction occurs (albeit at a lower level) even in subjects with higher intelligence. FGAs do not appear to impair or improve working memory in patients with schizophrenia. There is limited evidence to support clozapine’s role in enhancing working memory. Risperidone may improve aspects of working memory functions. Studies involving evaluation of working memory using neuroimaging, pharmacological models of schizophrenia, and neurochemical function should further our understanding of this manifestation of schizophrenia. Cognition in schizophrenia has become the new frontier with targets that may be amenable to psychopharmacological treatments. However, treatments studied thus far have failed to produce the magnitude of changes that would be clinically relevant.

Social Cognition

Theory of mind (ToM) refers to the ability to represent the mental states of others and/or to make inferences about another’s intentions. Overall, individuals with schizophrenia have impairments in ToM that appear to be independent from general cognitive abilities. Facial affect recognition deficits are stable in schizophrenia. ToM, attributional style and facial affect recognition are considered key domains of social cognition. These deficits in social cognition are in fact related to behavior. Changes in behavior that can be labeled as bizarre or deviant or abnormal precede the onset of psychosis and persist with significant variability and intensity throughout the course of illness. Recently there has been an increased recognition of social cognition and how it affects individuals with schizophrenia. Frith hypothesized that many symptoms typical of schizophrenia may be accounted for by a specific cognitive incapacity of schizophrenia patients to accurately attribute mental states to themselves or others, commonly referred to as ‘having a theory of self and others’ minds’ leading to what Frith called ‘disorders of willed action’, disorders of self monitoring’ and disorders of ‘monitoring other persons’ thoughts and intentions.’ Schizophrenia patients show significant deficits in recognizing other people’s emotions from facial expressions, gestures, or voices and inferring the mental states of others. Schizophrenia patients show problems in their ability to appreciate the mental states of others (emotion recognition). Some studies have shown that ToM had strong associations with executive functioning. Duration of illness had a fairly strong negative impact on the ToM performance but was unrelated to emotion recognition abilities. The evidence that the impairments in ToM skills are independent of general cognitive deficits is mixed. Facial affect recognition and social cue perception are two important areas in which there are significant and stable deficits (Brune and Brune-Cohrs 2006).

A number of studies suggest that there may be a decline in cognitive functioning around the prodrome with significant decline after the onset of psychosis. The FGA agents have minimal effect on the cognition. Longitudinally, improvements in psychotic symptoms do not correlate to improvement in cognition too. Some have found that over the course of a decade, in first episode patients, executive functions did not change but there was a decline in visual-spatial functioning. The course of neurocognitive impairment in elderly patients is uncertain, but this may also depend on the age of onset, chronicity of the illness, etc.

Cognitive dysfunction is not strongly correlated with severity of psychosis and positive symptoms, but does have significant correlation with various types of negative symptoms with modest effects. Thus, many believe that neurocognitive symptoms are not caused by psychosis. Thus changes in positive symptoms do not significantly improve cognition in schizophrenia. Some have blamed the side effects of the FGA on negatively affecting cognition. SGA agents were expected to improve cognition to a much better degree than the FGA. However, recent data from real world patients do not bear this out. If there are differences between FGAs and SGAs they are significantly small. Social and occupational functioning show strong association with cognitive functioning. Higher levels of cognitive impairments require greater amount of vocational support. Quality of life measures are also related to cognition.

Differential Diagnosis

Making an accurate diagnosis of schizophrenia requires high levels of clinical acumen, extensive knowledge of schizophrenia, and sophisticated application of the principles of differential diagnosis. It is unfortunately common for patients with psychotic disorders to be misdiagnosed and consequently treated inappropriately. The importance of accurate diagnosis is underlined by an emerging database indicating that early detection and prompt pharmacological intervention may improve the long-term prognosis of the illness.

Mental Status Examination

There is no specific laboratory test, neuroimaging study, or a diagnostic test that yields a definitive diagnosis of
Schizophrenia. At present, the diagnosis of schizophrenia is made on a clinical basis. Schizophrenia can present with a wide variety of symptoms, and a longitudinal history of symptoms and comorbid clinical variables such as medical illness and a history of substance abuse must be evaluated before a diagnosis can be considered. The Mental Status Examination, much like the physical examination, is an additional clinical tool that aids the psychiatrist in generating a differential diagnosis and appropriate treatment recommendations.

**Appearance**
Although a disheveled look is not pathognomonic for schizophrenia, patients with this disorder often present, especially acutely, with a disordered appearance. The description of a patient's appearance is an objective verbal sketch, much like the description of a heart murmur that can uniquely identify a particular patient.

A person with schizophrenia often has difficulty attending to activities of daily living, either because of negative symptoms (apathy, social withdrawal, or motor retardation) or because of the presence of positive symptoms, such as psychosis, disorganization, or catatonia, that interfere with the ability to maintain personal hygiene. Also, schizophrenia patients often present with odd or inappropriate attire, such as a coat and hat worn during the summer or dark sunglasses worn during an interview. It is generally thought that the inappropriate dress is a manifestation of symptoms such as psychosis, which can make patients quite cautious and guarded in their responses to questions.

**Attitude**
Individuals with schizophrenia may be friendly and cooperative, or they may be hostile, annoyed, and defensive during an interview. The latter may be secondary to paranoid symptoms, which can make patients quite cautious and guarded in their responses to questions.

**Behavior**
Schizophrenia patients can have bizarre mannerisms or stereotyped movements that can make them look unusual. Patients with catatonia can stay in one position for weeks, even to the point of causing serious physical damage to their body; for example, a patient who stands in one place for days may develop stress fractures, peripheral edema, and even pulmonary emboli. Patients with catatonia may have waxy flexibility, maintaining a position after someone else has moved them into it. Patients with catatonic excitement exhibit odd posturing or purposeless, repetitive, and often strange movements.

Behaviors seen in schizophrenia patients include choreoathetoid movements, which may be related to antipsychotic exposure but have been reported in patients even before antipsychotic use. Other behaviors or movement disorders may be seen as parkinsonian features, such as a shuffling gait or a pill-rolling tremor.

Psychomotor retardation may be present and may be a manifestation of catatonia or negative symptoms. On close observation, it is usually characterized, in this group of patients, as a lack of motor movements rather than slowed movements.

Patients may present with agitation, ranging from minimal to extreme. This agitation is often seen in the acute state and may require immediate pharmacotherapy. However, agitation may be secondary to antipsychotic medications, as in akathisia, which is felt as an internal restlessness making it difficult for the person to sit still. Akathisia can manifest itself in limb shaking, pacing, or frequent shifting of position. Severely agitated patients may be unresponsive to verbal limits and may require measures to ensure their safety and the safety of others around them.

**Eye Contact**
Paranoid patients may look hypervigilant, scanning a room or glancing suspiciously at an interviewer. Psychotic patients may make poor eye contact, looking away, or appear to stare vacuously at the interviewer, making a conversational connection seem distant. Characteristic responding to internal stimuli is seen when a patient appears to look toward a voice or an auditory hallucination, which the patient may hear. A nystagmus may also be observed. This clinical finding has a large differential diagnosis, including Wernicke-Korsakoff syndrome; alcohol, barbiturate, or phenytoin intoxication; viral labyrinthitis; or brain stem syndromes including infarctions or multiple sclerosis.

**Speech**
In a Mental Status Examination, one usually comments on the rate, tone, and volume of a patient's speech, as well as any distinct dysarthrias that may be present. Pressured speech is usually thought of in conjunction with mania; however, it can be seen in schizophrenia patients, particularly on acute presentation. This is often difficult to assess, as it may be a normal variant or a cultural phenomenon, because some languages are spoken faster than others.

Tone refers to prosody, or the natural singsong quality of speech. Negative symptoms may include a lack of prosody, resulting in monotonous speech. Furthermore, odd tones may be consistent with neurological disorders or bizarre behavior.

Speech volume is important for a number of reasons. Loud speech can be a measure of agitation, it can occur in conjunction with psychosis, or it could even be an indication of hearing loss. Speech that is soft may be an indication of guardedness or anxiety.

Dysarthrias are notable because they can be idiopathic and long-standing, or they can be an indication of neurological disturbance. In patients who have been exposed to antipsychotics, orobuccal tardive dyskinesia should be considered when there is evidence of slurred speech.

**Mood and Affect**
Affect, which is the observer's objective view of the patient's emotional state, is often constricted or flat in patients with schizophrenia. In fact, this is one of the hallmark negative symptoms. Flattened affect may also be a manifestation of pseudoparkinsonism, an extrapyramidal side effect of typical neuroleptics.

Inappropriate affect is commonly seen in patients with more predominant positive symptoms. A smile or a laugh while relating a sad tale is an example. Patients with catatonic excitement or hebephrenia may have bizarre presentations or affective lability, laughing and crying out of context...
might develop a delusion around a real physiological abnormality. Therefore, somatic symptoms should be evaluated appropriately in their clinical context without automatically dismissing them as psychotic. Preoccupations and obsessions are also seen commonly in this population, and certain patients have comorbid obsessive–compulsive disorder.

The mortality rate for suicide in schizophrenia is approximately 10%. It is therefore imperative to evaluate a patient for both suicidal and homicidal ideation. Patients of all diagnoses, and particularly schizophrenia, may not spontaneously articulate suicidal or homicidal ideation and must therefore be asked directly about such feelings. Moreover, psychotic patients may feel compelled by an auditory hallucination telling them to hurt themselves.

Perceptions
Perceptual disturbances involve illusions and hallucinations. Hallucinations may be olfactory, tactile, gustatory, visual, or auditory, although hallucinations of the auditory type are more typical of schizophrenia. Hallucinations in the other sensory modalities are more commonly seen in other medical or substance-induced conditions. Auditory hallucinations can resemble sounds, background noise, or human voices. Auditory hallucinations that consist of a running dialogue between two or more voices or a commentary on the patient’s behavior are typical of schizophrenia. These hallucinations are distinct from verbalized thoughts that most humans experience. They are often described as originating from outside the patient’s head, as if they were emanating from the walls or the radiators in the room. Less commonly, a patient with schizophrenia describes illusions or misperceptions of a real stimulus, such as seeing demons in a shadow.

Consciousness and Orientation
One of the observations that struck Kraepelin in his first descriptions of dementia praecox was that patients did not have clouding of consciousness. Patients with schizophrenia most likely have a clear sensorium unless there is some comorbid medical illness or substance-related phenomenon. A schizophrenia patient may be disoriented, but this could be a result of inattentiveness to details or distraction secondary to psychotic preoccupation. In fact, there is some literature suggesting that a subgroup of patients may present as disoriented to temporal relations such as the date or their own age.

Attention and Concentration
Studies utilizing continuous performance task paradigms have demonstrated repeatedly that schizophrenia patients have pervasive deficits in attention in both acute and residual phases. On a Mental Status Examination, these deficits may present themselves as the inability to perform mental exercises, such as spelling the word “earth” or “world” backward or performing serial subtractions.

Memory
Careful assessment of memory in patients with schizophrenia may yield some deficits. Acquisition of new information, immediate recall, and recent and remote memory may be impaired in some individuals. Furthermore, answers to questions regarding memory may lead to idiosyncratic responses related to delusions, thought disorder, or other overriding
symptoms of the illness. In general, schizophrenia patients do not show gross deficits of memory such as may be seen in patients with dementia or head trauma.

Fund of Knowledge
Schizophrenia is not the equivalent of mental retardation, although these syndromes can coexist in some patients. Patients with schizophrenia generally experience a slight shift in intellectual functioning after the onset of their illness, yet they typically demonstrate a fund of knowledge consistent with their premorbid level. Schizophrenia patients manifest a characteristic discrepancy on standardized tests of intelligence, with the nonverbal scores being lower than the verbal scores. Furthermore, some reports suggest that patients who have been chronically hospitalized or those with some cerebral atrophy may evidence diminished intellectual function.

Abstraction
A classical aberration of mental function in a patient with schizophrenia involves the inability to utilize abstract reasoning, which is similar to metaphorical thinking, or the ability to conceptualize ideas beyond their literal meaning. For example, when the patient is asked what brought him or her to the hospital, a typical answer might be “an ambulance.” On a Mental Status Examination, this concrete thinking is best elicited by asking a patient to interpret a proverb or state the similarities between two objects. For example, “a rolling stone gathers no moss” may mean, to the patient with schizophrenia, that “if a stone just stays in one place, the moss won’t be able to collect.” More profound difficulties in abstraction and executive function, often seen in schizophrenia, such as inability to shift cognitive focus or set, may be assessed by neuropsychological tests.

Judgment and Insight
Individuals suffering from schizophrenia often display a lack of insight regarding their illness. Whether it is a reflection of a negative symptom, such as apathy, or a constricted display of emotion, patients often appear to be emotionally disconnected from their illness and may even deny that anything is wrong. Poor judgment, which is also characteristic and may be related to lack of insight, may lead to potentially dangerous behavior. For example, a patient walking barefoot in the snow because of the feeling that her or his shoes could be traced by surveillance cameras would be displaying both poor judgment and poor insight. On a formal Mental Status Examination, judgment is commonly assessed by asking patients what they would do if they saw a fire in a movie theater or if they saw a stamped, addressed envelope on the street. Insight can be ascertained by asking patients about their understanding of why they are being evaluated by a psychiatrist or why they are receiving a certain medication.

Physical Examination
Although there are no pathognomonic physical signs of schizophrenia, some patients have neurological “soft” signs on physical examination. The neurological deficits include nonspecific abnormalities in reflexes, coordination (as seen in gait and finger-to-nose tests), graphesthesias (recognition of patterns marked out on the palm), and stereognosis (recognition of three-dimensional pictures). Other neurological findings include odd or awkward movements (possibly correlated with thought disorder), alterations in muscle tone, an increased blink rate, a slower habituation of the blink response to repetitive glabellar tap, and an abnormal pupillary response. The exact etiology of these abnormalities is unknown, but they have historically been associated with minimal brain dysfunction and may be more likely in patients with poor premorbid functioning and a chronic course. These neurological abnormalities have been seen in neuroleptic-naive patients as well as those with exposure to traditional antipsychotic medication. Overall, the literature suggests that these findings may be associated with the disease itself, although further research is needed to determine the role of neuroleptic exposure in the manifestation of neurological signs and the extent to which schizophrenia is itself associated with neurological abnormalities.

Additional Testing
The presentation of psychotic symptoms raises a broad differential diagnosis. Though a thorough history, mental status and physical examination are important, additional testing is utilized to help establish diagnoses of schizophrenia and other psychotic disorders. A thorough evaluation of psychotic symptoms would warrant baseline laboratory testing, including a toxicology screen, to rule out other conditions. In addition, EEG and MRI testing are useful to assess for underlying neurological disorders. Negative findings on EEG and MRI do not definitively rule out the possibility of other neurological conditions, though patients with schizophrenia and other psychotic disorders often do have essentially normal results on these tests. In addition, neuropsychological deficits seen in patients with schizophrenia can best be evaluated with neuropsychological testing. This type of testing can be quite useful in helping to establish diagnosis and baseline functioning, as well as in helping to assess for improvement over time.

Other Conditions That Resemble Schizophrenia

Schizoaffective Disorder
Possibly the most difficult diagnostic dilemma in cases in which a patient has both psychotic symptoms and affective symptoms are in the differentiation between schizophrenia and schizoaffective disorder. The term schizoaffective disorder was first coined by Kasanin (1933). Since then, there has been some controversy regarding this diagnostic entity. It has been included in studies of both affective disorder and schizophrenia and has at times been considered part of a continuum between the two, which has contributed to some of the diagnostic confusion.
In DSM-IV-TR, schizoaffective disorder is treated as a unique clinical syndrome. A patient with schizoaffective disorder must have an uninterrupted period of illness during which, at some time, they have symptoms that meet the diagnostic criteria for a major depressive episode, manic episode, or a mixed episode concurrently with the diagnostic criteria for the active phase of schizophrenia (criterion A for schizophrenia). Additionally, the patient must have had delusions or hallucinations for at least 2 weeks in the absence of prominent mood disorder symptoms during the same period of illness. The mood disorder symptoms must be present for a substantial part of the active and residual psychotic period. The essential features of schizoaffective disorder must occur within a single uninterrupted period of illness where the “period of illness” refers to the period of active or residual symptoms of psychotic illness and this can last for years and decades. The total duration of psychotic symptoms must be at least 1 month to meet the criteria A for schizophrenia and thus, the minimum duration of a schizoaffective episode is also 1 month.

The criteria for major depressive episode require a minimum duration of 2 weeks of either depressed mood or markedly diminished interest or pleasure. As the symptoms of loss of pleasure or interest commonly occur in nonaffective psychotic disorders, to meet the criteria for schizoaffective disorder criteria A, the major depressive episode must include pervasive depressed mood. Presence of markedly diminished interest or pleasure is not sufficient to make a diagnosis as it is possible that these symptoms may occur with other conditions too.

**Brief Psychotic Disorder and Schizophreniform Disorder**

The distinctions among brief psychotic disorder, schizophreniform disorder, and schizophrenia are based on duration of active symptoms. As discussed earlier, DSM-III adopted a 6-month rule from the St. Louis group criteria. DSM-IV has maintained the requirement of 6 months of active, prodromal, and/or residual symptoms for a diagnosis of schizophrenia. Brief psychotic disorder is a transient psychotic state, not caused by medical conditions or substance use, that lasts for at least 1 day and up to 1 month. Schizophreniform disorder falls in between and requires symptoms for at least 1 month and not exceeding 6 months, with no requirement for loss of functioning.
Delusional Disorder

If the delusions that a patient describes are not bizarre (e.g., examples of bizarre delusions include the belief that an outside force or person has taken over one’s body or that radio signals are being sent through the caps in one’s teeth), it is wise to consider delusional disorder in the differential diagnosis. Delusional disorder is usually characterized by specific types of false fixed beliefs such as erotomanic, grandiose, jealous, persecutory, or somatic types. Delusional disorder, unlike schizophrenia, is not associated with a marked social impairment or odd behavior. Moreover, patients with delusional disorder do not experience hallucinations or typically have negative symptoms.

Affective Disorder with Psychotic Features

If the patient experiences psychotic symptoms solely during times when affective symptoms are present, the diagnosis is more likely to be mood disorder with psychotic features. If the mood disturbance involves both manic and depressive episodes, the diagnosis is bipolar disorder. According to DSM-IV-TR, affective disorders that are seen in patients with schizophrenia may fall in the category depressive disorder not otherwise specified or bipolar disorder not otherwise specified.

General Medical Conditions

General medical conditions ranging from vitamin B₁₂ deficiency to Cushing’s syndrome have been associated with
a clinical presentation resembling that of schizophrenia. Because the prognosis for the associated medical condition is better than that for schizophrenia and the stigma attached to schizophrenia is significant, it is imperative to provide patients with a thorough medical work-up before giving a diagnosis of schizophrenia. This includes a physical examination; laboratory analyses including thyroid function tests, syphilis screening, and folate and vitamin B12 levels; a CT or MRI scan; and a lumbar puncture when indicated in syphilis screening, and folate and vitamin B12 levels; a CT or MRI scan; and a lumbar puncture when indicated in new-onset cases.

**Course of Illness**

The most influential model for the long-term course of schizophrenia was proposed by Kraepelin. Inherent in the term dementia praecox was the view that the course of this illness was similar to that of the dementias in that they were progressive with worsening over time. This downhill trajectory had profound clinical and research implications throughout the century. For example, if patients with schizophrenia recovered or even had a prolonged remission, it was generally considered that they had been erroneously diagnosed. Indeed, even in DSM-III, patients with schizophrenia were described as rarely recovering. Moreover, pathophysiological theories were influenced by this model in that disease processes that were progressive were given strong consideration.

The Kraepelinian model for this illness went essentially unchallenged for more than 50 years until well-designed epidemiological studies of schizophrenia were conducted. In long-term follow-up studies of 20 years or more, surprisingly favorable outcomes were observed: between 40 and 66% of patients had either recovered or were only mildly impaired at follow-up (Table 65–2). In the Vermont Longitudinal Study of Schizophrenia (Harding et al. 1987a, 1987b), 269 backward patients who were chronically institutionalized in the 1950s were followed up an average of 32 years later. The patients who met rigorously applied retrospective DSM-III diagnostic criteria for schizophrenia disorder (N = 118) during their index admission in the 1950s were found on follow-up to have outcomes that varied widely; 82% were not hospitalized in the year of the follow-up, 68% displayed slight or no symptoms, 81% were able to meet their own basic needs, and more than 60% had good social functioning. Thus, these data indicate that the long-term outcome of schizophrenia is heterogeneous, with substantially larger numbers of patients having better outcomes than would have been predicted by the Kraepelinian model.

Based on current epidemiological data, a new model of the natural course of schizophrenia has been proposed (Breier et al. 1991). This model has three phases: an early phase marked by deterioration from premorbid levels of functioning; a middle phase characterized by a prolonged period of little change termed the stabilization phase; and the last period, which incorporates the long-term outcome data just cited, which is called the improving phase (Figure 65–9).

**First Episode Schizophrenia**

An enormous clinical and research effort is directed internationally toward patients in very early stages of their illness and especially during their first psychotic break with a focus on early and effective intervention. First episode provides a unique opportunity to intervene early and effectively and possibly change the course of illness. It is well known that there is a delay of 1–2 years on an average between onset of psychosis and starting of treatment (Lieberman and Fenton 2000). This duration of untreated psychosis (DUP) has emerged as an independent predictor of likelihood and extent of recovery from a first episode of psychosis and possibly a modifiable prognostic factor. A large meta-analysis reported that shorter DUP was associated with greater improvement in severity of positive and negative symptoms as well as functional outcomes (Perkins et al. 2005). These associations were independent of the effect of other variables also associated with prognosis including premorbid functioning. In important and landmark studies done by the Norwegian Early Treatment and Intervention on Psychosis Program, they targeted general population, health professionals, schools and

other relevant establishment with a comprehensive multimedia educational program. Before the program, the DUP on an average was 114 weeks (median = 26 weeks). Following the program, the DUP was 26 weeks (median = 5 weeks) (Larsen et al. 2000). Emboldened by these findings, in a follow up study, they compared two areas in Norway with one receiving the intense community and professional education while the other did not. The median duration of DUP in the area with active educational program was 5 weeks and in the control area was 16 weeks implying that by mere spreading of information, psychoeducation and by having special programs, the DUP can be shortened with potential beneficial (possibly neuroprotective) effects on the course of illness. Additionally, the symptom severity and the 3-month clinical outcome were significantly better in the intervention program (Melle et al. 2004). These and other early and very early intervention programs are introducing the concept of “prevention” of morbidity related to schizophrenia, improving the course of schizophrenia and perhaps postponing the onset of illness significantly, a remarkably rare occurrence in the history of this devastating illness. Many such programs are now attempting innovative interventions (like the ones mentioned above) all over the world. The hope is that such programs will provide neuroprotection and eventually have an impact on suicidality too.

Larsen and colleagues (2000) examined 1-year outcome in 43 first episode patients and at 1-year follow-up 56% were in remission, 26% were still psychotic and 18% suffered multiple relapses. Both longer DUP and poor premorbid functioning predicted more negative symptoms and poor global functioning. Clinical deterioration appears to be correlated with the duration of psychosis and number of episodes of psychosis (Wyatt 1991). The deterioration usually occurs during the first 5 years after onset and then stabilize at a level where they have persistent symptoms and are impaired in their social and vocational function. After that point additional exacerbation may occur but they are not usually associated with further deterioration (Lieberman 1999a).

Long-term studies of schizophrenia suggest that negative symptoms tend to be less common and less severe in the early stages of the illness but increase in prevalence and severity in the later stages. Positive symptoms such as delusions and hallucinations are more common earlier on while thought disorganization, inappropriate affect, and motor symptoms occur more commonly in the later stages of illness. A possible decline in the prevalence of the hebephrenic and catatonic subtypes of schizophrenia may be attributed to effective treatment and possible arrest of the progression of illness. Thus with effective treatment, and with long-term compliance it is possible to produce favorable outcomes.

Following onset of the illness, patients experience substantial decline in cognitive functions from their premorbid levels. However, it is unclear whether, after the first episode, there is further cognitive decline due to the illness. Some studies even suggest a slight and gradual improvement. Increased number of episodes and the longer duration of untreated psychosis are associated with greater cognitive dysfunction.

Patients with first episode psychosis usually have excellent clinical response to antipsychotic treatment early in their course of illness when compared to chronic multi-episode patients. Effective and early intervention does help achieve clinical remission and good outcome (Lieberman 2006). Some suggest that SGAs should be used preferentially in the treatment of first episode patients with psychotic disorders (Lieberman 1996) as they are a highly treatment responsive group, and may be best able to optimize the outcome. In addition, first episode patients are sensitive to side effects, especially extrapyramidal and weight gain side effects. They require lower doses of medication to achieve therapeutic responses. The issue of treatment adherence is of critical importance in first episode patients. Although these patients respond very well with 1-year remission rates of greater than 80%, the 1-year attrition rates are as high as 60%. This important issue undermines management of first episode patients during this critical period of their illness.

According to Emsley et al. (2006), the most important factor by far in management of first episode patients is non and partial adherence to medication. Poor adherence is greatest early in the illness. Relapses and partial response result in accruing morbidity and enduring deficits in cognition and psychosocial function. In their 24-month study involving first episode patients with schizophrenia, schizophreniform and schizoaffective disorder, patients were treated with long acting risperidone every two weeks. Most patients showed clinical improvement with low relapse rates and low rates for treatment discontinuation for any reason. They had 86% retention rate. The authors suggest that rather than reserving the long-acting injectable antipsychotics for the chronic, difficult and poorly compliant patients, it is wiser to use it as a first line treatment whenever possible.

**Treatment**

It could be argued that the successful treatment of schizophrenia requires a greater level of clinical knowledge and sophistication than the treatment of most other psychiatric and medical illnesses. It begins with the formation of a therapeutic psychiatrist–patient relationship and must combine the latest developments in pharmacological and psychosocial therapeutics and interventions.

**Psychiatrist–Patient Relationship**

The psychiatrist–patient relationship is the foundation for treating patients with schizophrenia. Because of the clinical manifestations of the illness, the formation of this relationship is often difficult. Paranoid delusions may lead to mistrust of the psychiatrist. Conceptual disorganization and cognitive impairment make it difficult for patients to attend to what the psychiatrist is saying and to follow even the simplest directions. Negative symptoms result in lack of emotional expression and social withdrawal, which can be demoralizing for the psychiatrist who is attempting to “connect” with the patient.

It is important for the psychiatrist to understand the ways in which the psychopathology of the illness affects the therapeutic relationship. The psychiatrist should provide constancy to the patient, which helps “anchor” patients in their turbulent world. The qualities of the relationship should include consistency, acceptance, appropriate levels of warmth that respect the patient’s needs for titrating emotional intensity, nonintrusiveness, and, most important, caring. “Old-fashioned” family doctors who know their patients well, are easily approachable, have a matter-of-fact style, attend to a broad range of needs, and are available and willing to reach out during crises provide a useful model...
for the psychiatrist–patient relationship in the treatment of schizophrenia. With increasing medical morbidity secondary to lifestyle issues and side effects of medications, and recognition that persons with schizophrenia may be generally be at increased risk of medical morbidity, the psychiatrist also assumes more responsibilities of coordinating care across various disciplines, integrating discussions about ‘wellness’ along with illness management and heavily relying on this relationship to affect positive changes.

Psychopharmacological Treatment

Background
One hundred years ago, Philippe Pinel changed the philosophy of treating the mentally ill when he unchained patients and provided them with well-balanced diets in the hope that these interventions would ameliorate their symptoms (Weiner 1992). Attempts to treat these patients medically included interventions such as insulin shock, dialysis, and frontal lobotomies. These methods appeared effective at times, yet it was clear that something else was needed to help the poorly understood symptoms of schizophrenia.

It was mere serendipity when a surgeon in France, Henri Laborit, through his keen observations, recognized that chlorpromazine had unusual tranquilizing properties during its use as a preoperative anesthetic medication. This led to its first successful use in the treatment of psychosis as described in the seminal work of Delay and Deniker in 1952 which provided a pharmacological strategy that would forever change the face of schizophrenia. The implementation of chlorpromazine became the turning point for psychopharmacology. Patients who had been institutionalized for years were able to receive treatment as outpatients, and live in community settings. The road was paved for the deinstitutionalization movement, and scientific understanding of the pathophysiology of schizophrenia burgeoned.

The discovery of the first antipsychotic, chlorpromazine, a phenothiazine compound, led to the development of other phenothiazines and new classes of antipsychotic medications, now totaling 12 different classes available in the US today. The word neuroleptic, literally “nerve cutting” was used to describe the tranquilizing effects of these medications. The tremendous efforts to understand the mechanism of action of these (typical) antipsychotics uncovered the intimate association of dopamine D2 receptor blockade to the antipsychotic effects. This formed the basis of the original dopamine hypothesis suggesting that symptoms of schizophrenia were possibly related to the hyperactivity of the mesolimbic and mesocortical dopaminergic systems in the brain. Antipsychotics developed subsequent to chlorpromazine such as haloperidol, thiothixene, and so on, were modeled on the (misguided) belief that induction of EPS was an integral part of having an antipsychotic efficacy. Over the years another belief developed that all antipsychotics were similar in their efficacy and varied only in their side effects. However, the antipsychotic drug clozapine, which was available for clinical use since 1960s in Europe, challenged these beliefs by being significantly superior in efficacy than the existing antipsychotics and having minimal to no EPS! This started the era of antipsychotic agents being referred to as either “typical” (conventional or traditional) or “atypical” (or novel) antipsychotic drugs. If chlorpromazine started the first revolution in the psychopharmacological treatment of schizophrenia, then clozapine ushered in the second and more profound revolution whose impact is felt beyond schizophrenia and its full extent is yet to be realized. Moreover, clozapine invigorated the psychopharmacology of schizophrenia and rekindled one of the most ambitious searches for new antipsychotic compounds by the pharmaceutical industry. Following approval of clozapine in 1990, the FDA has already approved six new antipsychotics—risperidone (Risperdal 1994), olanzapine (Zyprexa 1996), quetiapine (Seroquel 1997), ziprasidone (Geodon 2001), aripiprazole (Abilify 2002), and paliperidone (Invega 2007)—and is on the verge of approving more, a remarkable progress indeed. Perhaps the best way to classify these medications would be to call the traditional, typical or conventional antipsychotics as first generation antipsychotics (FGA) and the atypical, novel or serotonin dopamine antagonists as Second Generation Antipsychotics (SGA).

It is indeed hard to believe that FGAs were the only medications available in USA until 1994, with the exception of clozapine, for treatment of schizophrenia. Furthermore, it is equally amazing how dramatically the SGAs have replaced the FGAs in last decade. However, FGAs are still an important and sometimes the only choice in many parts of the world. Clinicians, educators as well as most among the research community firmly believed that the nonclozapine SGAs were markedly superior compared to the FGAs. When a number of meta-analyses and reviews failed to find meaningful or substantial differences between the FGAs and nonclozapine SGAs, it was puzzling and not quite believable. Actually, the psychiatry community was so enamored with these medications with remarkably better neurological adverse events that the spending increased from $1.4 billion in 1994 to more than $10 billion dollars annually toward antipsychotic medication costs. According to Rosenheck (2006), the high expectations from the SGAs combined with the enthusiasm with which each new medication was greeted is evident in increased annual sales every year after their approval such that they became “the most widely prescribed on-patent psychotropic drugs, and as much as 100 times the cost of some FGAs.” Every new year saw SGAs eroding the market share of FGAs such that many believed it was only a matter of time before most of them would be out of use. However, data from two “practical clinical trials (discussed later, in Chapter 102)” and a study from VA medical center surprised the clinical and research community by failing to show meaningful differences in effectiveness, quality of life and other important outcome measures between FGAs and SGAs (excluding clozapine, aripiprazole and paliperidone) in nonrefractory patients (Lieberman et al. 2005, Jones et al. 2006, Rosenheck 2006, Lieberman 2006). When even treatment data from first episode studies failed to show substantial differences on efficacy and retention measures with some of the SGAs, the disappointment was palpable. Even the investigators of these studies were surprised by the results. These sobering results led Lieberman (2006) to conclude that the SGAs are not the “great breakthrough” in treatment as once thought but rather an “incremental advance” over the FGAs. However, there are others who do believe that the differences between the two groups of antipsychotic are sufficiently important to justify their preferential use.
Only time will tell if these data will lead to resurrection of FGAs clinically or a more gradual extinction. Many in the clinical and research community believe that both SGAs and FGAs have a place in the treatment of schizophrenia until we find dramatically better alternatives. There is no doubt that the FGAs are potent antipsychotic medications that play a major role in de-institutionalizing chronically ill schizophrenia patients and improving their quality of life; unfortunately, they also cause significant neurological side effects at therapeutic doses that are quite troubling. Increasingly, the opinions are converging on individualizing treatments for the patients that provide the most efficacy and least (or tolerable) side effects regardless of medication class utilized.

**First Generation Antipsychotic (FGA) Medications**

There are seven major classes of FGAs currently available in USA. *Phenothiazines* were the first antipsychotics used in treatment of schizophrenia. These tricyclic compounds can be further classified into three subgroups. *Aliphatic* phenothiazines are low potency antipsychotics like chlorpromazine and trifluromazine which are likely to be quite sedating and have substantial hypotensive and anticholinergic side effects. *Piperidine* phenothiazines include thioridazine which also causes sedation, hypotension and anticholinergic side-effects. Moreover, it is likely to substantially prolong QTc interval such that it now carries a ‘black box’ warning requiring mandatory EKG monitoring. *Piperazine* phenothiazines are more likely to produce EPS but less likely to produce drowsiness, anticholinergic side effects and hypotension. These are also the most popular FGA phenothiazines with compounds like fluphenazine, perphenazine and prochlorperazine.

Haloperidol, one of the most commonly used FGAs, belongs to *Butyrophenones* group. It is a potent dopamine D₂ receptor antagonist and thus more likely to cause acute dystonic reactions, EPS and TD. They do not cause anticholinergic and autonomic side effects. Haloperidol is also the most commonly used comparator antipsychotic drug in regulatory trials. Droperidol is another member of this group and was commonly used in ER to control agitation until it was reported to prolong QTc interval, cause *Torsades de Pointes* (ventricular arrhythmias), and sudden death. *Diphenylbutylpiperidines* share similarities with butyrophenones and pimozide is the only compound available from this group. Prolongation of QTc interval has emerged as a major concern limiting its use, though it is still popular in treatment of delusional disorders.

Chlorprothixene and thiothixene belong to *Thioxanthines* group and have side effects similar to the phenothiazines. Loxapine is the only *Dibenzoxapine* compound available in USA from this group; chemically it is a close cousin of clozapine but not clinically. Molindone, a representative *Dihydroindole* compound from this group, was widely used in individuals who gained weight on other antipsychotic medications.

**Clozapine and the Second Generation Antipsychotic (SGA) Medications**

Though clozapine, a dibenzodiazepine compound, was approved for use in the US in 1990, it had been available in European markets during the 1970s but had been found to be associated with agranulocytosis, a potentially fatal side effect, which led to its removal from clinical trials. The need for improved treatment of schizophrenia, particularly for patients who do not respond to FGAs, generated interest in resuming investigations of clozapine’s clinical efficacy.

Double-blind, controlled studies demonstrated the superior clinical efficacy of clozapine compared with FGAs, without the associated EPS (Kane et al. 1988, Breier et al. 1994). It is clearly superior to SGAs for psychosis. A summary of some of the US studies of patients with chronic and treatment-resistant schizophrenia suggests that approximately 50% of patients derive a better response from clozapine than from FGA (Table 65–3). Its effect on negative symptoms is controversial and has generated intense and passionate debates as to whether the efficacy of the medication is with primary or secondary negative symptoms or both. There is substantial evidence that clozapine decreases relapses, improves stability in the community, and diminishes suicidal behavior. It is the only antipsychotic that has received FDA approval for treating suicidal patients. There have also been reports that clozapine may cause a gradual reduction in preexisting tardive dyskinesia, improve tardive dystonia, decrease substance use, psychogenic polydipsia and cigarette smoking among schizophrenia patients.

Unfortunately, clozapine is associated with agranulocytosis, and because of this risk, it requires weekly to monthly white blood cell (WBC) testing. Approximately 0.8% of patients taking clozapine and receiving regular WBC monitoring develop agranulocytosis. Women and the elderly are at higher risk than other groups. The period of highest risk is the first 6 months of treatment. These data have led to monitoring of WBC counts less frequently after first 6 months to every other week if a person has a history of WBC counts within normal range in the preceding 6 months. After 1 year of WBC counts being in normal

</table>
range, the monitoring frequency decreases to once a month. Current guidelines state that the medication must be held back if the total WBC count is 3,000 mm\(^{-3}\) or less or if the absolute polymorphonuclear cell count is 1,500 mm\(^{-3}\) or less. Patients who discontinue clozapine treatment require blood monitoring for at least four weeks after the last dose. Other side effects of clozapine include orthostatic hypotension, tachycardia, sialorrhea, sedation, elevated temperature, weight gain, hyperglycemia, and hyperlipidemia. Furthermore, clozapine can lower the seizure threshold in a dose-dependent fashion, with a higher risk of seizures seen particularly at doses greater than 600 mg/day.

Clozapine has an affinity for dopamine receptors (D\(_1\), D\(_2\), D\(_3\), D\(_4\), and D\(_5\)), serotonin receptors (5-HT\(_{2A}\), 5-HT\(_{2C}\), 5-HT\(_{6}\), and 5-HT\(_{7}\)), alpha-1- and alpha-2-adrenergic receptors, nicotinic and muscarinic cholinergic receptors and H\(_1\) histaminergic receptors. As clozapine has a relatively shorter half-life, it is usually administered twice a day.

The superior antipsychotic efficacy of clozapine has inspired an abundance of research in the field of modern psychopharmacology for the treatment of schizophrenia. Clozapine and the other SGAs have an array of biochemical profiles, with affinities to dopaminergic, serotonergic, and noradrenergic receptors (Figure 65–10 [see Color Plate 000]). Research on the SGAs has led to a greater understanding of the biochemical effects of antipsychotic agents, leaving the basic dopamine hypothesis of schizophrenia insufficient to explain schizophrenia symptoms. Clozapine shows selectivity for mesolimbic neurons and does not increase the prolactin level. Binding studies have shown it to be a relatively weak D\(_1\) and D\(_2\) antagonist, compared with FGAs. Clozapine shares the property of higher serotonin 5-HT\(_{2A}\) to dopamine D\(_2\) blockade ratio reported to impart atypicals; thus, antipsychotics with this profile are often called serotonergic dopamine antagonists. The noradrenergic system may also have a role in the mechanism of action of clozapine. Clozapine, but not FGAs, causes up to fivefold increases in plasma norepinephrine. Moreover, these increases in norepinephrine correlated with clinical response. Clozapine is available in tablet form only.

Following clozapine, risperidone was the first SGA approved by FDA in 1994. Risperidone is a benzisoxazole compound with a high affinity for 5-HT\(_{2A}\) and D\(_2\) receptors and has a high serotonin dopamine receptor antagonism ratio. It has high affinity for alpha-1-adrenergic and H\(_1\) histaminergic receptors and moderate affinity for alpha-2-adrenergic receptors. Risperidone is devoid of significant activity against the cholinergic system and the D\(_3\) receptors. The efficacy of this medication is equal to that of other first-line SGAs and is well tolerated and can be given once or twice a day. The most common side effects reported are drowsiness, orthostatic hypotension, lightheadedness, anxiety, akathisia, constipation, nausea, nasal congestion, prolactin elevation, and weight gain. At doses above 6 mg/day EPS can become a significant issue. The risk of tardive dyskinesia (TD) at the regular therapeutic doses is low. Risperidone is also available in a liquid form, rapidly disintegrating tablets called M tablets and as a long acting intramuscular preparation called Risperdal Consta which is given every two weeks. Risperidone will be the second SGA available in a generic form starting 2008.

Olanzapine, a thienobenzodiazepine compound approved in 1996, has antagonistic effects at dopamine D\(_1\) through D\(_3\) receptors and serotonin 5-HT\(_{2A}\), 5-HT\(_{2C}\), and 5-HT\(_{6}\) receptors. The antiserotonergic activity is more potent than the antidopaminergic one. It also has affinity for alpha-1-adrenergic, M\(_1\) muscarinic acetylcholinergic and H\(_1\) histaminergic receptors. It differs from clozapine by not having high affinity for the 5-HT\(_{7}\), alpha-2-adrenergic, and other cholinergic receptors. It has significant efficacy against positive and negative symptoms and may improve cognitive functions. EPS is minimal when used in the therapeutic range with the exception of mild akathisia. As the compound has a long half-life, it is used once a day and as it is well tolerated, it can be started at a higher dose or rapidly titrated to the most effective dose. It is available as a rapidly disintegrating wafer form (Zyprexa Zydis), which dissolves immediately in the mouth. A short acting intramuscular form has also been approved by FDA. The commonly observed adverse events include weight gain, hyperglycemia, hyperlipidemia,
sedation, dry mouth, nausea, lightheadedness, orthostatic hypotension, dizziness, constipation, headache, akathisia, and transient elevation of hepatic transaminases. The risk of TD and NMS is low. Though used as a once-a-day medication, it is often administered twice a day with the average dose of 15 to 20 mg/day. However, doses higher than 20 mg/day are often used clinically (Volavka et al. 2002). In the CATIE study, patients received olanzapine up to 30 mg/day (Lieberman et al. 2005).

Quetiapine, a dibenzothiazepine compound approved in 1997, has a greater affinity for serotonin 5-HT₂ receptors than for dopamine D₂ receptors; it has considerable activity at dopamine D₁, D₃, D₄, serotonin 5-HT₁₅, and alpha₁-, alpha-2-adrenergic receptors. Unlike clozapine, it lacks affinity for the muscarinic cholinergic receptors. It is usually administered twice a day due to a short half-life. Quetiapine is as effective as FGAs and may improve cognitive function too. Among 2,035 patients enrolled in seven controlled studies, quetiapine at all doses used did not have an EPS rate greater than placebo. This is in contrast to olanzapine, risperidone, and ziprasidone, where there were dose related effects on EPS levels. The rate of treatment emergent EPS was very low even in high at-risk populations such as adolescent, parkinsonian patients with psychosis, and geriatric patients. There was no elevation of prolactin. Commonly observed adverse events include somnolence, postural hypotension, dizziness, agitation, dry mouth, and weight gain. Akathisia occurs on rare occasions. The package insert warns about developing lenticular opacity or cataracts and advises periodic eye examination based on data from animal studies. However, recent data suggest that this risk may be minimal. It is available as tablets and an extended release version is in development.

Ziprasidone, approved by FDA in 2001, has the strongest 5-HT₂ receptor binding relative to D₂ binding amongst the SGA agents currently in use. Interestingly, ziprasidone has 5-HT₁₅ agonist and 5-HT₁₀ antagonist properties with a high affinity for 5-HT₁₅, 5-HT₂₅, and 5-HT₁₀ receptors. As it does not interact with many other neurotransmitter systems, it does not cause anticholinergic side effects and produces little orthostatic hypotension and relatively little sedation. Just like some antidepressants, ziprasidone blocks presynaptic reuptake of serotonin and norepinephrine. Ziprasidone has a relatively short half-life and thus it should be administered twice a day and along with food for best absorption. Data for efficacy, side effects and dosing come from a number of studies. Ziprasidone at doses between 80 and 160 mg/day is probably the most effective for treating symptoms of schizophrenia. Ziprasidone pills should be taken with meals to obtain adequate blood levels. To assess the cardiac risk of ziprasidone and other antipsychotic agents, Pfizer and FDA designed a landmark study to evaluate the cardiac safety of the antipsychotic agents, given at high doses alone and with a known metabolic inhibitor in a randomized study involving patients with schizophrenia. This was done to replicate the possible worst-case scenario (overdose or dangerous combination treatment) in the real world. Some degree of QTc prolongation was observed with all antipsychotic agents. The least degree of QTc prolongation was observed with the oral form of haloperidol and the greatest degree with thioridazine (Figure 65–11). Commonly observed adverse events with the use of ziprasidone include somnolence, nausea, insomnia, dyspepsia, and prolongation of QTc interval. Dizziness, weakness, nasal discharge, orthostatic hypotension, and tachycardia occur less commonly.

Ziprasidone should not be used in combination with other drugs that cause significant prolongation of the QTc interval. It is also contraindicated for patients with a known history of significant QTc prolongation, recent myocardial infarction, or symptomatic heart failure. Ziprasidone has low EPS potential, does not elevate prolactin levels, and causes approximately 1 lb weight gain in short term studies (Allison et al. 1999). Ziprasidone is available in pill form and as a short-acting IM preparation.

When Arvid Carlsson, the Nobel Laureate and the original proponent of the dopamine theory of schizophrenia,
alluded to the possible advantages of a partial dopamine agonist at the Dopamine D2 autoreceptor in treatment of schizophrenia, scientists at Otsuka Pharmaceutical Co, Japan focused their efforts and developed OPC 14597, a partial dopamine agonist. After years of clinical trials and in collaboration with Bristol-Myers Squibb, it was approved for marketing as Aripiprazole in 2002. In a refreshing departure from other antipsychotics, it has a different mechanism of action where, as a partial agonist at the Dopamine D2 receptor, it behaves as a functional dopamine D2 antagonist in hyperdopaminergic environment and functional dopamine agonist in hypodopaminergic environment. This mechanism of action is thought to 'modulate' and 'stabilize' the dopaminergic system (see Figure 65–12). It is a serotonin 5-HT2A antagonist and partial agonist at 5HT1A receptor. It has moderate affinity for alpha 1 adrenergic and histaminergic H1 receptors with no significant effect at the anticholinergic receptors. Aripiprazole is a quinolinone compound and has a long half life of 75 hours. It is dosed once a day and is well absorbed orally and is not affected by administration of food. The advantages that aripiprazole offers as an antipsychotic medication are (a) it is perhaps the least sedating antipsychotic agent; (b) it does not increase prolactin levels, and may decrease the levels below baseline; (c) there is significantly less weight gain of 1 kg/year; (d) it does not elevate serum glucose levels; (e) it does not significantly elevate serum lipid levels; (f) it does not prolong QTc interval (g) and has relatively low rate of EPS. However, it does cause nausea during the early phase of the treatment and akathisia. As it is metabolized by CYP 3A4 and CYP 2D6, aripiprazole dose does require to be adjusted with CYP 3A4 inducers such as carbamazepine and CYP 3A4 and CYP 2D6 inhibitors such as fluoxetine. It is available in oral tablets, liquid and as short acting IM preparation.

Paliperidone or 9-hydroxy risperidone is an active metabolite of risperidone and was approved by FDA in 2006. It blocks the Dopamine D2 receptors along with serotonin receptors like its parent compound risperidone. It was significantly efficacious in double-blind, placebo controlled studies involving 1,248 subjects and a comparator arm of olanzapine. There was a 22% relapse rate compared to 52% on placebo after 52 weeks treatment. The prolactin levels were four times as high among men and five times as high among women who received paliperidone at any dosage. EPS such as dystonia and hyperkineses were more prevalent at 12 mg/day (10%) than 6 mg/day (5%). Tachycardia was more common than placebo. Paliperidone does not undergo hepatic metabolism thereby minimizing drug-drug interactions. Paliperidone ER is available using Osmotically controlled Release Oral-delivery System, or OROS formulation. There is an osmotic trilayer core, consisting of two distinct drug layers and an osmotic push layer. Good tolerance has been reported at 6, 9 and 12 mg/day.

The randomized controlled trials suggest that, on average, these antipsychotic agents are each associated with 20% improvement in symptoms. Recent studies and meta-analyses have given olanzapine an edge over the other SGAs except clozapine. However, treatment emergent weight gain and lipid elevations are the most commonly observed adverse events. Clozapine is the only antipsychotic agent that is more effective than most antipsychotics currently available in managing treatment resistant schizophrenia (Kane et al. 1988, McEvoy et al. 2006). Unfortunately, its potential for treatment-emergent agranulocytosis, seizures, and myocarditis, precludes its use as a first line agent for schizophrenia. A major difference amongst the newer antipsychotic agents is the side effect profile and its effect on the overall quality of life of the patient.

Acute Treatment

Until recently, the FGAs were the mainstay of the treatment for acute episodes of psychosis. In last decade, the use of SGAs has surpassed the use of FGAs in the management of acute phase symptoms of schizophrenia, except for the use of parenteral form of antipsychotics where FGAs still hold an upper hand. Interestingly, this trend has not changed as dramatically even with the availability of three injectable preparations for acute use of SGAs namely olanzapine, ziprasidone and aripiprazole (Keith 2006). The primary

**Figure 65–12** Aripiprazole: activity at dopend human D2 receptors.
goal of acute treatment is the amelioration of any behavioral disturbances that would put the patient or others at risk of harm. Acute symptom presentation or relapses are heralded by the recurrence of positive symptoms, including delusions, hallucinations, disorganized speech or behavior, severe negative symptoms, or catatonia. Quite frequently, a relapse is a result of antipsychotic discontinuation, and resumption of antipsychotic treatment aids in the resolution of symptoms. There is a high degree of variability in response rates among individuals. When pharmacotherapy is initiated, improvement in clinical symptoms can be seen over hours, days, or weeks of treatment.

Studies have shown that although FGAs are undoubtedly effective, a significant percentage (between 20 and 40%) of patients show only a poor or partial response to these agents. Furthermore, there is no convincing evidence that one FGA is more efficacious as an antipsychotic than any other, although a given individual may respond better to a specific drug. Some have suggested that clinical efficacy of thioridazine is different and better than the other FGAs and perhaps having an atypical profile. With so many antipsychotics available, making an informed choice between using an FGA or an SGA by the patient and the clinician should be based on efficacy, side effect profile, history of prior response (or nonresponse) to a specific agent, or history of response of a family member to a certain antipsychotic agent. For a pharmacotherapy decision tree for the treatment of schizophrenia, management of treatment-emergent side effects and associated or coexisting symptoms in schizophrenia based on Texas Medication Algorithm Project, see Figure 65–13 and Table 65–4 and Table 65–5. Amongst the FGAs, low-potency, more sedating agents, such as chlorpromazine, were long thought to be more effective for agitated patients, yet there are no consistent data proving that high-potency agents are not equally useful in this context. The low-potency antipsychotics, however, are more associated with orthostatic hypotension and lowered seizure threshold and are often not as well tolerated at higher doses. Higher potency antipsychotics, such as haloperidol and fluphenazine, are safely used at higher doses and are effective in reducing psychotic agitation and psychosis itself. However, they are more likely to cause EPS than the low potency agents and SGAs.

The efficacy of SGAs on positive and negative symptoms is comparable to or even better than the FGAs (see e.g., Lieberman et al. [1993], Chakos et al. [2001], Geddes et al. [2000], Lieberman et al. [2005], Jones et al. [2006]). The significantly low potential to cause EPS or dystonic reaction and thus the decreased long-term consequences of TD has made the SGAs more tolerable and acceptable in acute treatment of schizophrenia. Other significant advantages adding to the popularity of some of the SGAs include their beneficial impact on mood symptoms, suicidal risk, and cognition. They are significantly easy to use, have rapid action depending on the type of preparation used (e.g. liquid, rapidly disintegrating forms, or IM), and may have better side effects profile for acute treatment depending on the SGA used and allows for individualizing treatment. Thus, the selection of the first line treatment with antipsychotic will depend on the circumstances under which the medications are started, for example, extremely agitated or incompetent patients who are refusing court-mandated treatments or catatonic patients would require intramuscular preparation, rapidly disintegrating oral tablets or liquid preparation of antipsychotics. Recent data suggest that SGA IM preparations such as ziprasidone, olanzapine and aripiprazole may hold significant advantages over the IM FGAs such as haloperidol. However they are also significantly more expensive. Except for clozapine, which is not considered first line treatment because of substantial and potentially life threatening side effects, there is no convincing data supporting the preference of one FGA/SGA over the other. However, if the patient does not respond to one, a trial with another antipsychotic is reasonable and may produce response. Once the decision is made to use an antipsychotic agent, an appropriate dose must be selected. Initially, higher doses or repeated dosing may be helpful in preventing grossly psychotic and agitated patients from doing harm. In an open trial, 80 schizophrenic inpatients were assigned to receive haloperidol at a dose of 5, 10, or 20 mg/day for 4 weeks. In this study, the patients receiving the highest dose of haloperidol initially demonstrated the most effective treatment of psychotic symptoms, but they were later found to have a higher incidence of EPS and emotional withdrawal. In general, studies indicate that doses of high-potency antipsychotics such as haloperidol can be maintained at a total of 10 mg/day in an acute setting, and that there is no generalizable benefit of using higher doses. Early adjunctive treatment with anticholinergic medication may facilitate compliance with medication by decreasing intolerable side effects.

Some patients who are extremely agitated or aggressive may benefit from concomitant administration of high-potency benzodiazepines such as lorazepam, at 1 to 2 mg, until they are stable. Benzodiazepines rapidly decrease anxiety, calm the person, and help with sedation to break the cycle of agitation. They also help decrease agitation due to akathisia. The use of these medications should be limited to the acute stages of the illness to prevent tachyphylaxis and dependency. Benzodiazepines are quite beneficial in treatment of catatonic or mute patients but the results are only temporary though of enough duration to help with body functions and nutrition.

Maintenance Treatment
There is by now a great deal of evidence from long-term follow-up studies that patients have a higher risk of relapse and exacerbations if not maintained with adequate antipsychotic regimes (Hogarty et al. 1974). Noncompliance with medication, possibly because of intolerable antipsychotic side effects as well as other factors, may contribute to increased relapse rates. In a double-blind, placebo-controlled study of relapse rates, 50% of patients in a research ward demonstrated clinically significant exacerbation of their symptoms within 3 weeks of stopping antipsychotic treatment. Furthermore, in a comprehensive review of the literature on antipsychotic withdrawal examining 4,365 subjects, 53% of patients withdrawn from antipsychotics relapsed, compared with 16% of control subjects who were maintained with antipsychotic treatment. The length of follow-up was related to the risk of relapse. Unfortunately, in this review there were no clear demographical or clinical characteristics that consistently predicted relapse. Others have estimated that two-thirds of patients relapse after 9 to 12 months without antipsychotic medication, compared with 10 to 30%
who relapse when FGAs are maintained. Long-term outcome studies showed that persistent symptoms that do not respond to FGA therapy are associated with a greater risk of rehospitalization (Breier et al. 1991). Nonpharmacological interventions may help decrease relapse rates (discussed later). CATIE study and others have shown that almost 50 to 75% of subjects will switch or discontinue antipsychotic medications within first 18 months or less. This occurs even in medications with more favorable EPS profiles. However, even with the SGAs, compliance rates are not substantially better (Keith 2006).

Long-term treatment of schizophrenia is a complex issue. It is clear that the majority of patients require maintenance medication. Some patients do well with stable doses of antipsychotics for years without any exacerbations. However, many patients who are maintained with a stable
### Table 65–4  Management of Treatment-Emergent Side Effects in Schizophrenia

<table>
<thead>
<tr>
<th>Side Effect</th>
<th>Recommendations</th>
</tr>
</thead>
</table>
| **GI Upset**                          | - Nausea and diarrhea are usually transient side effects with antidepressants, and improvement should occur within 2–3 wk after initiation or dose increases.  
- Administer medication with food and large quantities of liquid.  
- Consider lowering dose, if possible, or slowing the dose titration.  
- Persistent GI upset may require changing to an alternative medication or adding an adjunctive agent, such as an H2 blocker (e.g., famotidine, ranitidine).  
- Enhanced physiologic tremor—A fine tremor of approximately 8–10 Hz; made worse with outstretched hands.  
  - Check blood levels of medication, if applicable.  
  - Decrease dose, divide dose, or change to slow release preparation of the medication.  
  - Propranolol can be given at 20–30 mg three times a day.  
- Parkinsonian tremor—Coarse tremor at rest of approximately 4–6 Hz.  
  - See treatment recommendations under extrapyramidal symptoms (EPS) below. |
| **Tremor**                            | - Enhanced physiologic tremor—A fine tremor of approximately 8–10 Hz; made worse with outstretched hands.  
- Parkinsonian tremor—Coarse tremor at rest of approximately 4–6 Hz.  
  - Decrease dose, divide dose, use bedtime dosing, or switch to alternate medication.  
  - Pharmacological treatments include benztropine 1–2 mg twice daily, diphenhydramine 25–50 mg two or three times daily, or propranolol 20–30 mg three times daily.  
  - Akathisia may respond to propranolol 20–30 mg three times a day. If this is not effective, alternatives include clonidine 0.1 mg three times a day, lorazepam 1 mg two or three times a day, or clonazepam 0.5–1 mg twice a day.  
- Dystonic reactions can often be prevented by benztropine 1 mg two or three times a day for the first few days of antipsychotic therapy. Acute dystonic reactions are generally managed with benztropine 1–2 mg IM or lorazepam 1–2 mg IM. |
| **Sedation**                          | - A thorough evaluation of sleep behaviors should be performed, including a patient assessment of sleep quality.  
- May try dosing medication at bedtime.  
- Decrease dose if possible.  
- Substitute a less sedating alternative medication.  
- Adjunctive medications may be considered. However, in patients with psychosis, adjunctive treatment is not recommended as it may possibly worsen the course of the episode.  
- Usually seen with typical antipsychotics or higher doses of risperidone.  
- Parkinsonian tremor—coarse tremor at rest of approximately 4–6 Hz.  
  - Decrease dose, divide dosing, use bedtime dosing, or switch to alternate medication.  
  - Pharmacological treatments include benztropine 1–2 mg twice daily, diphenhydramine 25–50 mg two or three times daily, or propranolol 20–30 mg three times daily.  
- Akathisia may respond to propranolol 20–30 mg three times a day. If this is not effective, alternatives include clonidine 0.1 mg three times a day, lorazepam 1 mg two or three times a day, or clonazepam 0.5–1 mg twice a day. |
| **Extrapyramidal symptoms (EPS)—Parkinsonian tremor, akathisia, and dystonia** | - Patients with a history of NMS should be educated about the need to stay well hydrated and avoid strenuous physical activity when outside during hot weather.  
- If the patient has been on a FGA, changing to a SGA is reasonable.  
- Prescribe typical antipsychotics in the lowest dose necessary for the shortest time possible. Mid-potency typical agents may be preferred if typical antipsychotic is selected.  
- Use atypical antipsychotic medications.  
- Consider clozapine which has an extremely low risk of TD.  
- Consider other treatment modalities, including ECT. |
| **Tardive dyskinesia**                | - May consider switching to an alternative medication with lower propensity to cause sexual dysfunction.  
- If SSRI-induced sexual dysfunction, may consider adding bupropion 75–150 mg daily.  
- Alternatives for the management of sexual dysfunction secondary to psychotropic medications is to add a selective phosphodiesterase (PDE) type 5 inhibitor. Use is contradicted with concurrent nitrates. Caution use with concomitant C4P3A4 inhibitors. Data available for use in females is limited to small, open label trials.  
- Sildenafil 25–100 mg one-half to 1 hr before sexual activity.  
- Tadalafil 10–20 mg one-half to 1 hr before sexual activity.  
- Vardenafil 5–20 mg one-half to 1 hr before sexual activity.  
- Other alternative is cyproheptadine 4–8 mg, given shortly before sexual intercourse. However, cyproheptadine is also a serotonin receptor antagonist, and frequent use in patients with affective symptoms should proceed with caution. |
| **Neuroleptic malignant syndrome (NMS)** | - May consider switching to an alternative medication with lower propensity to cause sexual dysfunction.  
- If SSRI-induced sexual dysfunction, may consider adding bupropion 75–150 mg daily.  
- Alternatives for the management of sexual dysfunction secondary to psychotropic medications is to add a selective phosphodiesterase (PDE) type 5 inhibitor. Use is contradicted with concurrent nitrates. Caution use with concomitant C4P3A4 inhibitors. Data available for use in females is limited to small, open label trials.  
- Sildenafil 25–100 mg one-half to 1 hr before sexual activity.  
- Tadalafil 10–20 mg one-half to 1 hr before sexual activity.  
- Vardenafil 5–20 mg one-half to 1 hr before sexual activity.  
- Other alternative is cyproheptadine 4–8 mg, given shortly before sexual intercourse. However, cyproheptadine is also a serotonin receptor antagonist, and frequent use in patients with affective symptoms should proceed with caution. |
| **Sexual dysfunction**                | - Encourage regular aerobic exercise at least four hours before bedtime.  
- Avoid alcoholic beverages.  
- Encourage regular sleep cycles.  
- Eliminate noises and distracting lights.  
- Engage in relaxing activities before bed (reading, sex, meditation, etc).  
- Try a glass of warm milk.  
- If due to concomitant antidepressant use: reduce the dose of antidepressant, if possible.  
- Try moving the dosing of the medication to the morning.  
- Adjunctive medications:  
  - Zolpidem 5–10 mg once daily at bedtime.  
  - Zaleplon 5–20 mg (10 mg recommended dose) once daily at bedtime.  
  - Eszopiclone 2–3 mg once daily at bedtime.  
  - Benzodiazepines, such as temazepam 15–30 mg once daily at bedtime or lorazepam 0.5–2 mg once daily at bedtime.  
  - Trazodone 25–100 mg once daily at bedtime.  
  - Low-dose tricyclic antidepressant, such as amitriptyline 10–50 mg once daily at bedtime.  
  - Brief, targeted cognitive therapy. |
| **Insomnia**                          | - Promote good sleep hygiene:  
  - Encourage regular aerobic exercise at least four hours before bedtime.  
  - Avoid alcoholic beverages.  
  - Encourage regular sleep cycles.  
  - Eliminate noises and distracting lights.  
  - Engage in relaxing activities before bed (reading, sex, meditation, etc).  
  - Try a glass of warm milk.  
- If due to concomitant antidepressant use: reduce the dose of antidepressant, if possible.  
- Try moving the dosing of the medication to the morning.  
- Adjunctive medications:  
  - Zolpidem 5–10 mg once daily at bedtime.  
  - Zaleplon 5–20 mg (10 mg recommended dose) once daily at bedtime.  
  - Eszopiclone 2–3 mg once daily at bedtime.  
  - Benzodiazepines, such as temazepam 15–30 mg once daily at bedtime or lorazepam 0.5–2 mg once daily at bedtime.  
  - Trazodone 25–100 mg once daily at bedtime.  
  - Low-dose tricyclic antidepressant, such as amitriptyline 10–50 mg once daily at bedtime.  
  - Brief, targeted cognitive therapy. |
antipsychotic dose have episodic breakthroughs of their psychotic symptoms. In a study by Hogarty and associates (1974), 374 schizophrenia patients were followed for 2 years after hospitalization and randomized to receive placebo alone, placebo and sociotherapy, chlorpromazine alone, or chlorpromazine and sociotherapy. In this study, the placebo-only group had a relapse rate that was almost twice that of the chlorpromazine-treated group. Unfortunately, the difficulties in tolerating antipsychotic side effects often contribute to medication noncompliance. Furthermore, intensive case management and rehabilitation counseling did prevent relapse but only after a delayed period. Sociotherapy and drug treatment were found to have additive effects in preventing relapse.

Given the findings of Hogarty and colleagues, it would be prudent to assess patients for medication compliance when signs of relapse are suspected. Prodromal cues may be present before an exacerbation of psychotic symptoms. For example, any recent change in sleep, attention to activities of daily living, or disorganization may be a warning sign of an impending increase in psychosis.

With the increase use of SGAs the widely anticipated improvement in compliance due to significantly less neurological side effects and possible beneficial effects on negative symptoms and neurocognition did not pan out (Lieberman 2006, Lieberman et al. 2005, Jones et al. 2006). In a landmark study comparing risperidone to haloperidol for effects on maintenance treatment, at the end of 1 year, patients taking risperidone were significantly better clinically, more patients were compliant with it and fewer patients had relapses. In this double blind prospective study, 397 stable outpatients were randomized to receive either risperidone or haloperidol for a minimum of 1 year. The Kaplan-Meier estimate of the risk of relapse at the end of study was 34% for the risperidone group and 60% for the haloperidol group. Early discontinuation of treatment for any reason was more frequent among haloperidol treated patients. Risperidone group had greater reductions in the mean severity of both psychotic symptoms and extrapyramidal side effects than those in the haloperidol group (Csernansky et al. 2002). This led to an FDA indication for its use in maintenance treatment. Long-term use of olanzapine, quetiapine, aripiprazole and ziprasidone are also reported to have significant beneficial effects either in comparison to placebo or an FGA like haloperidol. Reviewing all the data would be beyond the scope of this chapter. However, some of the important studies are reviewed in Chapter 102. The data from treatment with clozapine suggest its significant superiority compared to other treatments. In the treatment refractory patients, long-term randomized trials found significant reduction in rehospitalization and suicide rates (Meltzer and Okayli 1995).

For patients for whom compliance is a problem, long acting preparation of antipsychotics are available in the US for fluphenazine, haloperidol and risperidone. The antipsychotic drug fluphenazine or haloperidol is esterified in an oily solution which is injected every 1 to 6 weeks to circumvent the need for daily oral antipsychotic medications in most cases (although some patients benefit from adjuvant oral medication). This form of medication delivery guarantees that the medication is in the system of the person taking it and eliminates the need to monitor daily compliance. This alternative should be considered if noncompliance with oral agents has led to relapses and rehospitalization. With these patients, maintenance treatment using long-acting preparations should begin as early as possible. In a meta analysis done by Adams and colleagues (2001), 3,348 patients were randomized in trials of fluphenazine decanoate. The study attrition rates were remarkably low at only 14% of those randomized compared to 40 to 60% in trials of oral SGA agents. Depot antipsychotic drugs are effective maintenance therapy for patients with schizophrenia. However, currently we only have esters of 2 SGAs and thus the significantly elevated risk of bothersome neurological side effects is an unfortunate limitation to their use. Fortunately, the recent approval of long acting risperidone (Risperdal Consta), the only long-acting SGA currently available should improve the situation. Unlike the decanoate compounds, here risperidone is encapsulated into microspheres made of biodegradable polymer suspended in an aqueous diluent. After injection, very little active moiety is released for up to three weeks and thus oral therapy should be continued during this period. With repeated administration every two weeks, steady state plasma levels are reached after 4th injection and are maintained for 4-6 weeks after last injection. Compared to the daily immediate-release oral therapy, treatment with risperidone consta is associated with reductions in peak blood levels of approximately 30% and also decreased plasma peak-to-trough ratios by 32-42% and may cause fewer adverse effects. Long term data report significant decrease in hospitalization rates from baseline to the end of the

In general, treatment emergent side effects should be addressed first by dose reduction or medication switching. Prescribing medications for side effects may lead to new side effects. Benzodiazepines are best avoided in patients with prior history of substance abuse/dependence or who are at risk for substance abuse. Nonaddicting agents are preferred.
Management of Associated or Coexisting Symptoms in Schizophrenia

Benzodiazepines are best avoided in patients with prior history of substance abuse/dependence or who are at risk for substance abuse. Nonaddicting agents are preferred.

A study with a better tolerability profile than the FGAs. There is likely to be significantly higher rates of compliance to this treatment.

Many studies have investigated appropriate maintenance doses of FGAs. Effective maintenance treatment is defined as that which prevents or minimizes the risks of symptom exacerbation, relapse and subsequent morbidity. A series of interesting dose-finding studies were performed to determine the minimal dosage required to prevent relapse and to reduce the risk of extrapyramidal symptoms and tardive dyskinesia. The relapse rate (56%) of patients treated with lower doses of fluphenazine decanoate (1.25–5 mg every 2 weeks) was significantly greater than the relapse rate (14%) of patients receiving standard doses (12.5–50 mg every 2 weeks). Other investigators have found that this low dosage range may appear to prevent relapse for a certain period but fails to do so if patients are followed up for more than 1 year. Unfortunately, no specific dosage reliably prevents relapse, and there is no way to predict future relapse. This is true for the SGAs as well.

Plasma drug levels and their correlation with clinical response have also been considered in determining dosage requirements. However, the results remain controversial. Some studies have found that levels that were in excess of a certain therapeutic window led to an exacerbation of symptoms. There is no strong evidence with which to sort out whether this finding was indeed a result of higher plasma levels, secondary to higher dosing for treatment-resistant patients, or due to the fact that the side effects associated with higher doses of antipsychotics may mimic exacerbations of...
the primary illness. At this time, plasma drug levels are not recommended for dosage determination. They are clinically useful, however, for confirming compliance with medication and may provide information regarding toxicity or altered metabolism.

Thus the question comes up, are nonclozapine SGAs better than the FGAs in management of schizophrenia? There is no doubt of superiority of clozapine in patients who are (1) treatment refractory (2) hostile and aggressive (3) suicidal (4) concurrently using drugs and alcohol (5) having polydipsia and water intoxication and (6) intolerant to neurological side effects of other antipsychotic agents.

Some reviews of the literature comparing SGAs and FGAs have reported that they are generally equivalent in terms of efficacy against positive symptoms. Others have, using meta-analyses, raised concerns about the size and significance of the effects of SGA superiority over FGAs. Davis and Chen (2005) reviewed the data and divided the SGAs into three groups based on how effective they were. Amongst the antipsychotics available in USA, clozapine was in group one and clearly more effective than FGAs by about 0.5 effect size units. Risperidone and olanzapine were in the intermediate group as being more effective than FGAs. Aripiprazole, quetiapine and ziprasidone were in the third group which was not superior to FGAs. Furthermore, they suggest that these results were not likely due to higher and unfavorable doses of FGAs. They report that the relapse rate on placebo is 10% per month. Based on the pooled results of long-term maintenance studies from approximately 50 randomized controls of FGAs versus placebo, maintenance treatment reduced relapse quite substantially to one third. Again, they add that great majority of these relapses could have occurred because of poor compliance. As there are limited data of long term maintenance treatment they believe that even the limited data support that SGAs are better than FGAs in the maintenance treatment of schizophrenia as restoration of social functions, better efficacy against negative symptoms, depression and thought disorder may favor their use (Davis and Chen 2005).

Thus data from clinical trials provide confusing and inconsistent results. When 42 head-to-head studies of SGAs were analyzed, there appeared to be a bias in industry-sponsored studies where in 90% of the studies supported by pharmaceutical companies, the outcome favored the sponsoring company. To address such shortcomings including study design issues, NIMH embarked on its most ambitious and expensive project called clinical antipsychotic trials of intervention effectiveness (CATIE), see Chapter 102.

**Depression and Schizophrenia**

Symptoms of depression occur in a substantial percentage of schizophrenia patients with a wide range of 7 to 75% and a modal rate of 25% and are associated with poor outcome, impaired functioning, suffering, higher rates of relapse or rehospitalization, and suicide (Siris 2000). It is important to distinguish depression as a symptom or as a syndrome when it occurs. There is an important overlap of symptoms of depression with the negative symptoms. Differentiating these states can sometimes be difficult especially in patients who lack the interpersonal communication skills to articulate their internal subjective states well. Studies have failed to find significant gender differences in prevalence of depression in schizophrenia. This is interesting as in affective disorders more women suffer from depression compared to men. In hospitalized patients with acute exacerbation of depression in women was closely associated with higher negative symptoms scores and younger age whereas in men, positive symptoms and shorter hospitalization were the main factors associated with depression. An increased risk of suicide has been reported for the period immediately after discharge from hospital especially in those patients who have comorbid depression. Survival times from last admission to suicide were significantly shorter in depressed males compared to depressed females with schizophrenia. However, survival times from last hospitalization to suicide between depressive and nondepressive male patients with schizophrenia was significant; this was not the case for females. Thus, hospitalization provides an important opportunity for implementing suicide prevention program that can be followed post discharge. A link between FGAs and depression has been suggested with some considering depression to be a form of medication induced akinesia. Specifically, during treatment with FGAs, less responsive depressive symptoms are revealed and appear to increase as the positive symptoms subside. The SGAs appear to have better efficacy in treating depressive symptoms when compared to placebo as well as FGAs; however, recent studies have failed to find significantly lower levels of depression during treatment with SGAs. Many patients have a reaction of disappointment, a sense of loss or powerlessness, or awareness of psychotic symptoms or psychological deficits that contributes to depression. Depression in schizophrenia is heterogeneous and requires careful diagnostic clarification. DSM-IV-TR suggests that the term “Post psychotic depression” be used to describe depression that occurs at any time after a psychotic episode of schizophrenia, even after a prolonged interval. However, a large number of patients still end up with a depression that will require treatment with an antidepressant, though results concerning combination treatment using antipsychotics and antidepressants are ambiguous. Clearly, optimizing antipsychotic treatment is a very important first step. SSRIs provide a safer and more tolerable profile compared to the tricyclic antidepressants. Combining cognitive behavioral therapy with pharmacotherapy may augment clinical response. In rare circumstances, ECT may be necessary especially if the patient is deemed to be a high suicide or self-harm risk.

**Risks and Side Effects of FGAs**

Extrapyramidal symptoms are side effects more commonly associated with FGA medications that include dystonias, oculogyric crisis, pseudoparkinsonism, akinesia, and akathisia. They are referred to collectively as extrapyramidal symptoms or EPS because they are mediated or at least in part by dopaminergic transmission in the extrapyramidal system (see Figure 65–14). Prevalence rates vary among the different types of extrapyramidal symptoms. When present, they can be uncomfortable for the patient and a reason for noncompliance.

Dystonias are involuntary muscular spasms that can be brief or sustained, involving any muscle group. They can occur with even a single dose of medication. When they develop suddenly, these spasms can be quite frightening to the patient and potentially dangerous, as in the case of laryngeal dystonias. They are more likely to be seen in
neuroleptic malignant syndrome (NMS) is a relatively rare but serious phenomenon seen in approximately 1% of patients taking FGAs. It can be fatal in 15% of cases if not properly recognized and treated. Because the symptoms of NMS may reflect multiple etiologies, making diagnosis difficult, Levenson has proposed clinical guidelines. According to Levenson, three major or two major and four minor manifestations are indicative of a high probability of NMS. Major manifestations of NMS comprise fever, rigidity, and increased creatine kinase levels, and minor manifestations include tachycardia, abnormal blood pressure, tachypnea, altered consciousness, diaphoresis, and leukocytosis. Others do not subscribe to the major-minor manifestation distinctions. In general, NMS is considered to be a constellation of symptoms that usually develops during 1–3 days. Although its pathogenesis is poorly understood, it has been associated with all antidopaminergic antipsychotic agents and presents at any time during treatment. It must be distinguished from other clinical entities, including lethal catatonia, malignant hyperthermia, and serotonin syndrome.

The mainstay of treatment of NMS is cessation of antipsychotic therapy and supportive care, including intravenous hydration, reversal of fever with anti-pyretics and cooling blankets, and careful monitoring of vital signs because of the risk of cardiac and respiratory disturbance. Rhabdomyolysis is one of the most serious sequelae of NMS; it can lead to renal failure unless patients are well hydrated. In some cases, dantrolene and bromocriptine have been reported to be effective pharmacological treatments. Though quite rare, NMS has been reported even with the use of SGAs. The decision to rechallenge the patient with antipsychotics after an episode of NMS must be made with caution. Given the potential risk involved, informed consent related to a rechallenge is important, and should be obtained unless there is a valid clinical or legal basis that it would not be required.

One of the major risks of antipsychotic treatment, especially with the FGAs is that of TD, a potentially irreversible syndrome of involuntary choreoathetoid movements and chronic dystonias associated with long-term antipsychotic exposure. These buccal, orofacial, truncal, or limb movements can be exacerbated by anxiety and disappear during sleep. They can present with a range of severity, from subtle tongue movements to truncal twisting and pelvic thrusting movements and even possible respiratory dyskinesias. The prevalence rates for this syndrome range from less than 10 to more than 50%, but it is generally accepted that the risk increases 3–5% per year for each year the patient is treated with FGAs. Older age is a considerable risk factor for TD, and there is some evidence that women are at increased risk to more than 50%, but it is generally accepted that the risk increases 3–5% per year for each year the patient is treated with FGAs. Older age is a considerable risk factor for TD, and there is some evidence that women are at increased risk

![Figure 65-14](image)

**Figure 65-14** Relation of dopamine D₂ occupancy to CGI-rated clinical response (a) and prolactin level (b) among patients with first-episode schizophrenia receiving haloperidol. Dotted line in (a) indicates 78% of D₂ occupancy, which was associated with a significantly greater likelihood of extrapyramidal side effects or akathisia. Dotted line in (b) indicates 72% D₂ occupancy, which was associated with a significant greater likelihood of hyperprolactinemia. (Source: Kapur S, Zipursky R, Jones C, et al. [2000] Relationship between D₂ occupancy, clinical response, and side effects: A double-blind PET study of first-episode schizophrenia. American Journal of Psychiatry 157, 514–520. Copyright 2000 American Psychiatric Association; http://ajp.psychiatryonline.org. Reprinted by permission.)

young patients. Studies differ as to whether the prevalence is higher in males or females. Prevalence rates for dystonias secondary to FGA exposure range from 2 to 20%. They occur less commonly with SGAs.

Akathisia affects more than 20% of patients taking FGA medications. This clinical entity presents as motor restlessness or an internal sense of restlessness. Often patients experiencing akathisia are unable to sit still during an interview. Akathisia is difficult to differentiate from agitation. The tendency to treat agitation with antipsychotics may exacerbate akathisia, making treatment decisions challenging.

Treatment of acute dystonic reactions usually involves acute intramuscular administration of either an anticholinergic or diphenhydramine. Akathisia may not respond to anticholinergic medications. Both antipsychotic dosage reduction and the use of beta-blocking agents such as propranolol have been found to be efficacious in the treatment of akathisia.

Neuroleptic malignant syndrome (NMS) is a relatively rare but serious phenomenon seen in approximately 1% of patients taking FGAs. It can be fatal in 15% of cases if not
of TD or in the case of clozapine no risk of TD. In many instances, clozapine (and possibly quetiapine or olanzapine) may be the best treatment that can be offered for the TD itself. Unfortunately, there is no specific treatment of TD, although some investigators have proposed the use of adrenergic agents such as clonidine, calcium channel blockers, vitamin E, benzodiazepines, valproic acid, or reserpine to reduce the spontaneous movements.

Side Effects of Second Generation Antipsychotic Agents

One of the most significant advantages of the newer antipsychotic agent is the relatively less risk of developing EPS and TD. However, treatment emergent substantial weight gain is a harbinger for long-term health consequences and frequently a commonly reported reason for noncompliance with medication. Accumulated data from multiple studies report that treatment emergent weight gain is observed mostly with clozapine and olanzapine, quetiapine, risperidone and paliperidone are intermediate and then ziprasidone and aripiprazole (see Figures 65–15 and 65–16). Patients with schizophrenia, independent of the use of antipsychotic agents are at higher risk of developing diabetes mellitus relative to the general population (Dixon et al. 2000, Thakore et al. 2002). The data from Patient Outcome Research Team (PORT) suggest that the rate of diabetes mellitus and obesity amongst patients with major mental illness was substantially higher even before the advent of the SGA. This was more so in women and nonwhite population (Dixon et al. 2000). Thakore and colleagues (2002) investigated visceral fat distribution in drug-naïve and drug-free patients with schizophrenia. Compared to controls, patients with schizophrenia had central obesity and significantly higher levels of plasma cortisol. Thus patients with schizophrenia are at a higher risk to develop major medical problems even before they are exposed to antipsychotic medications.

However, higher rates of diabetes have been reported from treatment with several SGAs, including clozapine (see Figure 65–17), olanzapine, risperidone and quetiapine (Lambert et al. 2006). In 2003, an FDA warning for hyperglycemia and diabetes mellitus was added to the package insert of all SGAs. It stated that “hyperglycemia, in some cases extreme and associated with ketoacidosis or hyperosmolar coma or death, has been reported in patients treated with atypical antipsychotics. Assessment of the relationship between atypical antipsychotic use and glucose abnormalities is complicated by the possibility of an increased background risk of diabetes mellitus in patients with schizophrenia and the increasing incidence of diabetes in the general population. Given these confounders, the relationship between atypical antipsychotic use and hyperglycemia-related adverse events is not completely understood. Epidemiological studies suggest an increased risk of treatment-emergent hyperglycemia-related adverse events in patients treated with the atypical antipsychotics. Precise estimates for hyperglycemia-related adverse events in patients treated with atypical antipsychotics are not available.” Additional guidance is provided to clinicians regarding monitoring and management of hyperglycemic related events. The potential risk of treatment emergent weight gain, diabetes (type II) and metabolic syndrome may result from changes in glucose metabolism and insulin resistance. In approximately 25-40% of the cases of hyperglycemia, insulin resistance appears to occur even in absence of significant weight gain raising some interesting questions about how these medications may interact with the insulin-glycemic control. An alternative hypothesis that may account for some of these cases is that patients were prediabetic or undiagnosed with diabetes prior to SGA administration.

Hyperlipidemia is commonly observed with SGA treatment especially in women (Figure 65–18; Olfson et al. 2006); significant elevations of serum triglycerides are reported following SGA treatment. Baseline data from CATIE study suggest that the rate of DM was 12.5%, hyperlipidemia at 53% and hypertension at 37% but a significant number of these individuals were not receiving medical treatment for the same. At baseline, significantly large groups of subjects were already obese or over weight. Patients treated with olanzapine had the highest mean weight gain of 0.9 kg/month amongst all antipsychotic studied; about 30% subjects treated with olanzapine gained 7% or more weight from baseline compared with 7% to 16% with other treatment groups (Lieberman et al. 2005). Greater increases in glycosylated hemoglobin, total cholesterol and triglycerides were observed with olanzapine compared to other study drugs. Improvement in each metabolic variable was reported with ziprasidone treatment. In a subgroup of 689 subjects from CATIE study, 41% subjects met criteria for metabolic syndrome at baseline. Schizophrenia is already associated

![Figure 65–15 Clinically significant (≥7%) weight gain during antipsychotic treatment.](image-url)
with high mortality rate and this dramatic increase in obesity and metabolic syndrome in this group further increases risk of medical morbidity and mortality. Moreover, heavy smoking rates and unhealthy lifestyle only compounds the grim picture. Metabolic issues are also evident during treatment of first episode patient with SGAs. Sharing this concern, numerous monitoring guidelines have been recommended by various groups and countries (see Table 65–6) specifically suggesting assessments to be done at the time of starting antipsychotics especially SGAs and promoting ongoing assessments prospectively.

In the USA, a conference of experts in psychiatry and medicine was held at Mount Sinai in 2002 where specific recommendations were made regarding obesity, diabetes, hyperlipidemia and other health-related concerns regarding persons with schizophrenia (Marder et al. 2004). Similarly, American Diabetes Association, American
Psychiatric Association, the American Association of Clinical Endocrinologists, and the North American Association for the Study of Obesity also provided consensus guidelines (see Figure 65–19). Mount Sinai group also recommended interventions for management of weight gain and metabolic syndrome (see Figure 65–20; Covell et al. 2006). Many studies are indicating that these weight gains are reversible when switched to another antipsychotic. Mean weight reductions of approximately 10 kg with switch from olanzapine and 7 kg when switched from risperidone have been reported. However, switching medications is not always easy as it may result in relapse. When switching antipsychotic for management of side effects, the following table provides guidelines (Table 65–7; Weiden et al. 2006).

Amongst the SGAs, risperidone (and paliperidone), due to its potent dopamine D₂ blockade, remove the inhibitory dopaminergic tone in the tuberoinfundibular neurons resulting in significant increase in prolactin levels. This increase in prolactin is significantly more than usually seen with the FGAs. It is likely that the serotonin system is also involved along with dopamine in raising the prolactin levels. Clozapine and quetiapine, on the other hand, are less potent at the D₂ receptors and thus are less likely for treatment emergent prolactin elevations. In some individuals, these elevations of prolactin lead to amenorrhea, galactorrhea, gynecomastia, and may possibly decrease bone mineral density. Ziprasidone and olanzapine treatment emergent prolactin levels are not significantly increased within the therapeutic dose range. Aripiprazole, due to its unique effects on dopamine receptors, does not increase the prolactin levels and may in fact decrease them from baseline.

### Treatment Resistance and Negative Symptoms

The concept of treatment resistance has entered into common clinical judgment with the burgeoning interest in SGA, particularly clozapine. Treatment resistance was originally defined for research purposes (Kane et al. 1988). Patients who had failed to respond to or could not tolerate adequate

trials of FGA from three different biochemical classes and who had a clinically significant psychopathology rating based on the Brief Psychiatric Rating Scale qualified as treatment resistant. However, this research definition did not necessarily encompass patients who, by clinical standards, would meet the definition of treatment resistance. Marder and Van Putten (1988) suggested that backward schizophrenia patients, who are severely symptomatic or with severe TD or EPS, especially those with suboptimal responses to FGA agents, should be eligible for a trial of clozapine. One might also think of clinical treatment resistance as seen in patients who had an early age of illness onset with subsequent repeated hospitalizations and antipsychotic trials and who cannot achieve a level of social and occupational function commensurate with their age and level of education.

The concept of treatment resistance has undergone significant modification in recent years and is reviewed by Conley and Kelly (2001). The original concept of treatment refractory applied to the use of FGA agents. With the advent of the SGAs (which were generally thought to be more effective than the FGAs), the patient should fail at least one SGA agent before initiating a trial of clozapine mainly to avoid its side effects. The definition of the duration of a drug trial has also evolved over the years. It is increasingly appreciated that a 4–6 weeks duration of treatment with an antipsychotic agent at therapeutic doses can be considered an adequate trial. The recommended dosing has also undergone changes. The original recommendation considered a trial of 1,000 mg equivalent of chlorpromazine as a necessary minimum requirement but this threshold is now reduced to 400–600 mg/day equivalent based on the knowledge that these doses block enough dopamine D2 receptors with higher doses providing no additional benefit. Thus, a 4–6 weeks trial of 400–600 mg

- **Baseline measures of weight, glucose and lipids**
  - **Overweight?**
    - Yes: Use caution when prescribing drugs with increased risk of weight gain.
    - No: Weight at every visit for the first 6 mo*
  - **Hyperglycemia?**
    - Yes: At high risk of diabetes or experiencing weight gain?
      - Yes: Test glucose in 4 mo
      - No: Hyperglycemic?
        - Yes: Test glucose yearly
        - No: Test lipids every 6 mo
    - No: Weight gain (at least 1 BMI)?
      - Yes: Initiate plan to manage weight gain. Consider medication change if drug carries higher risk of weight gain. Weigh every visit until stabilized then every 3 mo
      - No: Plan to measure weight every 3 mo (more often if patient is overweight)
  - **Elevated lipid levels?**
    - Yes: Refer to a medical care provider. If not possible, recommend diet changes and/or prescribe cholesterol lowering drug
    - No: Refer to a medical provider

*If visits infrequent, ask for phone reports of weight change.*
of chlorpromazine equivalent is accepted as an adequate antipsychotic trial.

In treatment refractory patients, FGA use results in a less than 5% response rate (Kane et al. 1988). Clozapine is the only antipsychotic drug proven more efficacious in rigorously defined treatment refractory groups. Chakos and colleagues (2001) did a meta-analysis of 12 controlled studies involving 1,916 patients. Seven studies involved clozapine. The data showed that treatment resistant schizophrenia patients had more favorable outcomes when treated with clozapine rather than an FGA agent. However, monitoring of blood counts and fear of its side effects makes it one of most underused effective treatment for schizophrenia.

There is a dearth of good clinical data that indicates how effective risperidone is in this group. In one well-controlled double-blind study, risperidone was more effective and better tolerated than haloperidol though the efficacy was not comparable to clozapine. Two other studies have compared risperidone to clozapine in refractory patients and showed the efficacy of risperidone to be similar to clozapine but, the definition used of “treatment refractory” status and the study design are either not comparable or have limitations. From these and other open label-studies, risperidone appears to be superior to FGAs in treatment refractory patients but does not appear to be as efficacious as clozapine.

Olanzapine has been reported to have better outcome than haloperidol in the treatment-resistant schizophrenia group from a double-blind study. However, when olanzapine was compared to chlorpromazine in a treatment refractory group using a double-blind study design, the outcome with olanzapine was not comparable to what is typically seen with the use of clozapine. When patients refractory to olanzapine in this trial were subsequently treated with clozapine, the response rate was similar to what is seen with the use of clozapine in treatment-refractory group. Similar findings were reported from an open label study of olanzapine in a treatment refractory group. Thus, it appears that though olanzapine was better than FGAs it was not as efficacious as clozapine for treatment refractory patients. However,
these studies were conducted using the standard doses of olanzapine. Recent studies using higher doses of olanzapine up to 50 mg/day appear to be better and comparable to clozapine in efficacy (Volavka et al. 2002) suggesting that the treatment refractory group may need higher doses of olanzapine to have a meaningful outcome.

Negative symptoms, such as apathy, amotivational syndrome, flattened affect, and alogia, are often the most problematic for patients with schizophrenia, accounting for much of the morbidity associated with this illness. In addition, these symptoms are often the most difficult to treat and do not respond well to FGAs. The SGAs are perhaps more effective against the negative symptoms than the FGAs (Kane et al. 1988). However, the magnitude of the effect of these compounds on primary negative symptoms is not clear. Amisulpiride, an SGA that is not available in USA, has been extensively studied against core negative symptoms with a meta-analysis suggesting a small but significant effect size compared with placebo (r=0.26; p<0.0001) but not FGAs (Leucht et al. 2002). Clozapine has been extensively used in treatment of negative symptoms with significant impact on general negative symptoms though its effect on primary negative symptoms is disputed. Data about risperidone and olanzapine use are mixed. SSRIs in combination with antipsychotic medications have shown mixed but encouraging results (see Murphy et al. 2006). They also observe that prevalence of deficits symptoms are lower in first episode patients compared to chronic patients suggesting progression of the underlying etiology and raising questions about the duration of negative symptoms also affecting the antipsychotic efficacy. Overall, they found the quality of studies done in this area poor and disappointing (Murphy et al. 2006). Clearly, one of the goals of psychopharmacological research is to develop new antipsychotic agents with low associated risk, a more effective treatment for negative and cognitive symptoms, a further reduction in positive symptoms, and an improvement in long-term relapse rate for patients with chronic schizophrenia.

Use of Concomitant Psychotropic Medications (CPM) with Antipsychotics

Concomitant Psychotropic Medications or CPM use during treatment of schizophrenia has dramatically increased worldwide. However, CPM use can increase side effects, cause drug interactions, escalate treatment costs, and lead to nonadherence. CPM use has come under criticism especially when the data supporting their use are equivocal or limited. Multinational and large studies have reported 53–92% of subjects using CPM. In the NIMH sponsored CATIE study, the baseline mean CPM use was 2.03 ± 1.10. Being anxious, depressed, female or using SGA were strongest predictors of taking multiple CPMs while African Americans or individuals with better neurocognitive functioning were less likely to take several CPMs at CATIE study baseline. Some studies reported higher CPM use with SGA while others had contradictory results. CPM use was lower in those who were employed. One study reported fewer adverse reactions, shorter length of hospital stay, increase discharges to community rather than to state hospitals with increase CPM use. However, when antidepressants and mood stabilizers were gradually tapered off at one center in stable patients, in most circumstances there were no untoward effects raising concern that CPM were either used for a duration longer than what was needed or they were not at all necessary in the first place. On the other hand, the number of CPM prescribed may closely relate to the severity of the patient’s illness.

When data of each CPM class used are reviewed, sedative/anxiolytics (SA) were the most commonly used CPMs in most studies with inpatient use as high as 90% and outpatient use up to 47%. SA use varied with the antipsychotic used and was significantly greater with risperidone, quetiapine, and oral FGAs compared to olanzapine after 6 months of treatment in one study. However, SA dose was twice as high for olanzapine group compared to clozapine with suicide attempters receiving higher doses than non attempters in the InterSePT study. Women were significantly more often treated with SA than men. At an academic institution practicing evidence based medicine, SA use increased significantly from 76% in 1989 to 90% in 2001 and appeared to increase concurrently with the increase SGA use. SA use decreased from baseline to prospective study points in many studies indicating possible state specific short-term need for SA use. Benzodiazepines, when added to antipsychotic medications during acute treatment, were reported to be beneficial and additionally appeared to reduce anxiety, insomnia, agitation, and psychotic symptoms. Comorbid anxiety disorder and individuals with higher positive symptoms scores were more likely to receive sedative hypnotics. Higher number of depression symptoms also predicted higher benzodiazepine use.

The preferential use of SGA over FGA in last decade has resulted in significant decrease in anticholinergic (ACH) use. When evidence based medicine was practiced, ACH use decreased from 48% in 1989 to 14% in 2001 which was similar to baseline CATIE use of 15%. ACH use may worsen positive symptoms, as well as cognition but it does provide relief from parkinsonian symptoms.

Antipsychotic (AP) polypharmacy varies significantly based on stage of illness, severity and geographical location amongst other factors. At baseline, 5% subjects in CATIE study were receiving polypharmacy, while other studies reported a wide range from 7% to 90%. Males were associated with an increased likelihood of receiving long term AP polypharmacy. Lower neurocognitive scores were more likely to be associated with polypharmacy while older age, minority status, and comorbid depression or substance abuse were generally less likely to be associated with AP polypharmacy. Many recent studies have reported mixed results supporting concomitant use of two antipsychotic drugs.

Antidepressants (AD) were used in 9.5–25% subjects at baseline in the SOHO study with similar rates at 6 months across antipsychotic treatments. Female gender and presence of depressive symptoms was associated with greater use of AD. Although there is some evidence that FGAs themselves cause depression, there undoubtedly are schizophrenia patients who have primary depressive symptoms. Surprisingly, SGAs were significantly linked to AD use whereas FGAs were not. AD was more often prescribed to those who were unemployed, received more psychotropics and had milder positive symptoms. Comorbid conditions such as major depression, OCD and other anxiety disorder independently predicted adjunctive AD treatment at baseline in the CATIE study. Data from metaanalyses and review
of literature are not convincing that AD use in schizophrenia is helpful. AD medications have also been considered in the treatment of depression associated with schizophrenia. Negative symptoms are often difficult to distinguish from depression (both have features of amotivation, apathy, and social withdrawal), but those that are secondary to depression may respond to the addition of an antidepressant to the patient’s medication regimen.

One study reported higher rates of mood stabilizer use in 2000 compared to 1995 even when there was corresponding increase in SGA use. Presence of depressive symptoms and hostility were associated with use of mood stabilizers in the SOHO study. Female gender predicted lithium use and higher positive symptoms predicted adjunctive mood stabilizer use at CATIE baseline. In a meta-analysis, lithium augmentation was found to be superior to placebo when added to an antipsychotic drug; however, the superiority of lithium augmentation was only of borderline statistical significance when participants with schizoaffective disorders were excluded. Depakote augmentation merely provided more rapid response to treatment with antipsychotic drug. There appeared no additional benefits.

When agonists of the glycine site of the NMDA receptor were added to FGAs in a placebo-controlled study, significant improvement were reported in negative symptoms and aspects of cognitive functioning. D-cycloserine, a partial agonist at the glycine site produced a selective improvement of negative symptoms at six weeks. Augmentation with another endogenous full agonist, d-serine was associated with significant improvement in negative, positive, and cognitive symptoms when added to conventional agents in an eight-week trial. Recently, a large study using ampanike CX 516 in some of the SGAs did not improve negative as well as cognitive symptoms in four weeks.

### Treatment Adherence

To achieve short and long-term goals of a treatment plan successfully in a patient suffering from schizophrenia, adherence to pharmacological as well as nonpharmacological interventions is pivotal. Data from 11 studies and 2,032 patients showed a relapse rate of 15% in people treated with SGA versus 23% in FGAs. Data from California Medicaid patients showed direct correlation between estimated partial adherence and hospitalization risk across a continuum of adherence behaviors from 1 to 10 days (Weiden 2006). Data from VA suggest that those with 100% compliance had significantly less hospitalization rates. In one study, poor adherence to antipsychotic treatment increased risk for suicide attempts up to 4 fold.

When patient’s attitudes toward antipsychotic medications were assessed in 228 subjects, they highly correlated both with insight and positive relationships with staff. The quality of patient’s relationships with clinicians during an acute admission was critical toward forming their attitudes toward their medication and adherence. Psychosocial interventions, especially psychoeducation for patients and family are effective avenues to improve adherence and reduce relapse and readmission rates. However, despite the effectiveness of psychoeducation, the number of family members and patients exploiting this approach is quite low (Kane 2006). In cases where there is a high risk of noncompliance or partial compliance, long-acting injectable antipsychotics can help improve adherence and reduce relapse and hospitalization rates. This mode of medication administration can detect noncompliance early, reliably and provide an opportunity to intervene when the medication is still in the person’s system (Kane 2006). If schizophrenia is progressive and has neurodegenerative components and treatments for schizophrenia have neuroprotective effects (by arresting gray matter loss in important areas of the brain) either as a primary effect or secondary to prevention of relapses, then treatment adherence provides perhaps the most important opportunity to optimize these imperfect treatments. Otherwise, these losses may not be reversible.

### New Directions

Psychopharmacological research has focused on developing compounds with unique combinations of effects at these different neurotransmitter sites. Future strategies for the treatment of schizophrenia are based on novel constructs of its pathophysiology.

Neurocognitive impairments have now become the core feature of schizophrenia. In response to the identification of the bottleneck limiting the development of treatments specifically directed at the cognitive deficits in schizophrenia, NIMH developed Measurement And Treatment Research to Improve Cognition in Schizophrenia (MATRICS) program. The MATRICS program is set out to develop a broad consensus regarding the nature of the cognitive impairments in schizophrenia and how they might be best assessed and treated. Thus, there is a paradigm shift here such that the cognitive symptoms are treated separately from psychotic symptoms. MATRICS has identified domains of cognition deemed most relevant in schizophrenia. Experts from academia and industry met to identify the most intriguing molecular targets, promising compounds, relevant human test measures, and potentially predictive animal models for use in the discovery of treatments related to complex cognitive operations. Subsequently they developed a beta version of the MATRICS Consensus Cognitive Battery for Clinical Trials. The group had meetings focused on collaborations between the NIMH, FDA and industry. They have successfully addressed the obstacles to developing preclinical drugs. There is a lot of hope and promise invented in their efforts to develop a breakthrough in this area.

One area of interest involves the glutamatergic system. Glutamate, the major excitatory neurotransmitter in the brain, is implicated in information processing and memory, functions that are impaired in schizophrenia. PCP, an NMDA antagonist, causes a syndrome with symptoms clinically similar to those of schizophrenia. These observations have led to the hypothesis that the glutamatergic NMDA receptor is involved in the pathophysiology of schizophrenia. Investigation of compounds like CX516 that alter NMDA receptor activity is under way to learn more about the clinical significance of this neurotransmitter system.

Based on compelling evidence implicating the alpha-7 nicotinic receptor in the pathophysiology of schizophrenia, a proof of concept trial was conducted to determine if DMXB-A, a natural alkaloid derivative and partial alpha-7 nicotinic cholinergic agonist, was effective for cognitive impairment in patients with schizophrenia (Olincy et al. 2006). Significant cognitive improvement was reported.
which provides preliminary support for the alpha-7 nicotinic receptor as a viable target for a novel treatment for schizophrenia. Replication in a larger sample of patients with longer treatment durations is needed to confirm these data.

In another area of drug development, researchers are studying G proteins, ubiquitous proteins found on cell membranes, where they play a critical role in second-messenger systems. These proteins have been found to be related to dopamine receptors in schizophrenic patients and to be involved in the mechanism of action of lithium in the treatment of bipolar disorder. Advanced genetic technology using techniques that could lead to altered receptor function “upstream” is also being explored. Given the enhanced understanding of influential biochemical, genetic, and neurodevelopmental interactions, there is promise of developing treatment strategies that would provide a more effective, safe means of ameliorating both the positive and negative symptoms of schizophrenia.

There is tremendous interest in early identification of potential subjects who may go on to develop schizophrenia. Attempts are underway to understand possible role for use of various treatment interventions before the onset of psychosis such that there can either be delay in onset of psychosis and possible change in the course of illness for the better.

**Nonpharmacological Treatment of Schizophrenia**

**Background**

Although psychopharmacological intervention has proved to be the foundation on which the treatment of schizophrenia depends, other approaches to the management of these patients serve a critical function. Studies have shown repeatedly that symptoms of schizophrenia have not only a genetic component but also an environmental aspect, and interactions with family and within the community can alter the course of the illness.

For many years, a dichotomous view of treatment options was tenaciously debated as dynamic psychiatry was challenged by developments in the neurosciences. A more unified view is now accepted, as it has become clear that psychopharmacological treatment strategies are most efficacious if combined with some type of psychosocial intervention and vice versa. It can be said that because of the chronic nature of schizophrenia, one or more treatments may be required throughout the illness and they are likely to have to be modified as symptoms change over time.

**Psychosocial Rehabilitation**

Bachrach has defined psychosocial rehabilitation as “a therapeutic approach that encourages a mentally ill person to develop his or her fullest capacities through learning and environmental supports” (Bachrach 2000). According to the author, the rehabilitation process should appreciate the unique life circumstances of each person and respond to the individual’s special needs while promoting both the treatment of the illness and the reduction of its attendant disabilities. The treatment should be provided in the context of the individual’s unique environment taking into account social support network, access to transportation, housing, work opportunities, and so on. Rehabilitation should exploit the patient’s strengths and improve his/her competencies. Ultimately, rehabilitation should focus on the positive concept of restoring hope to those who have suffered major setbacks in functional capacity and their self-esteem due to major mental illness. To have this hope grounded in reality, it requires promoting acceptance of one’s illness and the limitations that come with it. While work offers the ultimate in sense of achievement and mastery, it must be defined more broadly for the mentally ill and should include prevocational and nonvocational activities along with independent employment. It is extremely important that work is individualized to the talents, skills, and abilities of the individual concerned. However, psychosocial rehabilitation has to transcend work to encompass medical, social, and recreational themes. Psychosocial treatment’s basic principle is to provide comprehensive care through active involvement of the patient in his or her own treatment. Thus, it is important that a holding environment be created where patients can safely express their wishes, aspirations, frustrations, and reservations such that they ultimately mold the rehabilitation plan. Clearly, to achieve these goals, the intervention has to be ongoing.

Given the chronicity of the illness, the process of rehabilitation must be enduring to encounter future stresses and challenges. These goals cannot be achieved without a stable relationship between the patient and rehabilitation counselor, which is central to an effective treatment and positive outcome. Thus, psychosocial rehabilitation is intimately connected to the biological intervention and forms a component of the biopsychosocial approach to the treatment of schizophrenia. In the real world, programs often deviate from the aforementioned principles and end up putting excessive and unrealistic expectations on patients, thus achieving exactly the opposite of the intended values of the program (see Bachrach (2000) for more details).

**Psychodynamic Approach**

Many attempts have been made to understand the psychodynamic implications and meaning of schizophrenic symptoms. To mention all of the contributors who laid the foundations of psychodynamic theory is beyond the scope of this work. However, several names are important to put this vast field into historical perspective. Adolph Meyer (1866–1950), for example, contributed to our appreciation of a longitudinal, rather than a cross-sectional, perspective of the patient. He was one of the first to consider that maladjustment early on may have some influence on later psychotic development (Arieti 1955). In his work with patients, Sigmund Freud (1855–1939) thought that schizophrenia was an illness that represented a regression and a subsequent turning away from social supports because of unresolved conflicts. He observed that these patients had difficulties in developing transference, which was a necessary step to effective analysis. Freud concluded that patients with schizophrenia could not benefit from this treatment (Gabbard 1990). Carl Jung (1875–1960) concentrated specifically on the psychotic content, looking for symbolic meaning through word association tests while working with schizophrenia patients at the Bergozoli Hospital in Switzerland. He believed that humans shared images and mythological symbols or archetypes through a collective unconscious, which was reflected in the psychotic
processes of the individual with schizophrenia (Arieti 1955). Harry Stack Sullivan (1892–1949) focused his life’s work on interpersonal therapy with schizophrenia patients. He thought that even the most severe schizophrenia patient was capable of a relational attachment (Arieti 1955, Gabbard 1990).

Psychotherapeutic technique held promise for many years as a potential for unraveling the mystery of individuals’ symptoms, with the hope of improvement in course and symptoms and even cure. Based on derivations of the classical analytical school, symptoms of schizophrenia were thought of in terms of conflict and defense mechanisms. For example, when paranoid patients believe they are being preyed on, they are projecting onto others their own internal, unconscious wish to kill. Thus, unconscious conflicts became manifest as psychotic symptoms. To the psychodynamic therapist then, affectively laden material elicits an increase in thought disorder or psychotic responses, as it touches on the patient’s unconscious feelings. These conceptualizations of schizophrenia influenced early work with these patients.

Although the psychodynamic understanding of intrapsychic events has been of historical interest, the application of traditional psychodynamic principles as primary treatment modalities is not recommended. One of the first studies that compared outcomes between medication-treated patients and psychotherapy-treated patients was conducted at the Camarillo State Hospital in 1968. This study found that the group of patients who received antipsychotic medication showed greater improvement than those who received psychotherapy alone. Subsequent studies have replicated these findings even when different types of therapy are examined. Evidence suggests that insight-oriented individual psychotherapy may not be as helpful for patients with schizophrenia as supportive, goal-directed individual therapy combined with medication treatment and social skills training.

Individual Psychotherapy
Individual therapy in a nontraditional sense can begin on meeting a patient. Even the briefest of normalizing contacts with an agitated, acutely psychotic patient can have therapeutic value. Psychodynamic interpretations are not helpful during the acute stages of the illness and may actually agitate the patient further. The psychiatrist using individual psychotherapy should focus on forming and maintaining a therapeutic alliance (which is also a necessary part of psychopharmacological treatment) and providing a safe environment in which the patient is able to discuss symptoms openly. A sound psychotherapist provides clear structure about the therapeutic relationship and helps the patient to focus on personal goals.

Often, a patient is not aware of or does not have insight into the fact that some beliefs are part of a specific symptom. A psychotherapist helps a patient to check whether his or her reality coincides with that of the therapist. The therapeutic intervention then becomes a frank discussion of what schizophrenia is and how symptoms may feel to the patient. This objectifying of psychotic or negative symptoms can prove of enormous value in allowing the patient to feel more in control of the illness. A good analogy is to diabetic patients, who know they have a medical illness and are educated about the symptoms associated with exacerbation. Just as these patients can check blood glucose levels, schizophrenia patients can discuss with a therapist their sleep patterns, their interpersonal relationships, and their internal thoughts, which may lead to earlier detection of relapses.

Schizophrenia often strikes just as a person is leaving adolescence and entering young adulthood. The higher the premorbid level of social adjustment and functioning, the more devastating and confusing the onset of symptoms becomes. Young male patients with a high level of premorbid function are at increased risk of suicide, presumably in part because of the tremendous loss they face. These feelings can continue for years, with schizophrenia patients feeling isolated and robbed of a normal life. Therefore, a component of individual work (which can also be achieved to some degree in a group setting) with these patients is a focus on the impact schizophrenia has had on their lives. Helping patients to grieve for these losses is an important process that may ultimately help them achieve a better quality of life.

Group Psychotherapy
Acutely psychotic patients do not benefit from group interaction. In fact, a quiet place with decreased social contact is most useful until medications have controlled acute symptoms. It is common in inpatient settings to slowly integrate patients into the ward community only as they appear less agitated and are able to remain in good behavioral control with improvement in psychotic symptoms. As their condition improves, inpatient group therapy prepares patients for interpersonal interactions in a controlled setting. After discharge, patients may benefit from day treatment programs and outpatient groups, which provide ongoing care for patients living in the community.

Because one of the most difficult challenges of schizophrenia is the inherent deficits in relatedness, group therapy is an important means of gathering patients together and providing them with a forum for mutual support. Insight-oriented groups may be disorganizing for patients with schizophrenia, but task-oriented, supportive groups provide structure and a decreased sense of isolation for this population of patients. Keeping group focus on structured topics, such as daily needs or getting the most out of community services, is useful for these patients (Gabbard 1990). In the era of community treatment and brief hospitalizations, many patients are being seen in medication groups, which they attend regularly to discuss any side effects or problems and to get prescriptions.

Cognitive behavioral group therapy (CBGT) is an important adaptation to provide CBT to a larger group when there are not many trained therapists. A systematic review on this topic was recently done. Out of 168 papers, 5 studies met the review criteria. CBGT was more effective than treatment as usual in reducing social anxiety and depression (Lawrence et al. 2006).

Psychoeducational Treatment
One of the inherent deficits from which schizophrenia patients suffer is an inability to engage appropriately in social or occupational activities. This debilitating effect is often a lasting feature of the illness, despite adequate psychopharmacological intervention. This disability often isolates patients and makes it difficult for them to advocate appropriate social
support or community services. Furthermore, studies have found that there is a correlation between poor social functioning and incidence of relapse. One of the challenges of this area of study is the great deal of variability in individual patients. However, standardized measures have been developed to ascertain objective ratings of social deficits. These assessments have become important tools in the determination of effective nonpharmacological treatment strategies.

The literature suggests that schizophrenia patients can benefit from social skills training. This model is based on the idea that the course of schizophrenia is, in part, a product of the environment, which is inherently stressful because of the social deficits from which these patients suffer. The hypothesis is that if patients are able to monitor and reduce their stress, they could potentially decrease their risk of relapse.

For this intervention to be successful, patients must be aware of and set their own goals. Goals such as medication management, activities of daily living, and dealing with a roommate are achievable examples. Social skills and deficits can be assessed by patients’ self-report, observation of behavioral patterns by trained professionals, or a measurement of physiological responses to specific situations (e.g., increased pulse when asking someone to dinner). Patients can then begin behavioral training in which appropriate social responses are shaped with the help of instructors.

One example of such a program, discussed by Liberman and colleagues (1986), is a highly structured curriculum that includes training manual, audiovisual aids, and role-playing exercises. Behaviors are broken down into small bits, such as learning how to maintain eye contact, monitor vocal volume, or ameliorate body language. The modules are learned one at a time, with role playing, homework, and feedback provided to the participants. In several studies, Liberman and coworkers have shown that patients who were treated with social skills training and medication spent less time hospitalized, with fewer relapses than those treated with holistic health measures (e.g., yoga, stress management) on 2-year follow-up. Research such as this in the field of social skills training is growing as the inherent deficits in information processing, executive function, and interpersonal skills are further elucidated.

Earlier studies have suggested that educational interventions influence both knowledge and drug use errors. Similarly, patient education improves compliance. Merinder (2000) reviewed patient education in seven randomized trials, four naturalistic studies and eight studies with mixed samples. The author concludes that knowledge and compliance can be improved by the interventions used and in some circumstances, relapse and symptomatology can be partly influenced. The didactic format influences knowledge more readily while interventions with behavioral contents influence compliance. Patient education programs tend to use more didactic interactive format, enabling a more thorough negotiation of illness attitudes.

Social Skills Training

In large number of patients, deficits in social competence persist despite antipsychotic treatment. These deficits can lead to social distress whereas social competence can alleviate distress related to social discomfort. The “token economy” programs with operant conditioning paradigms were used in past to discourage undesirable behavior. However, nowadays there are better ways to deal with these behaviors. Paradigms using instruction, modeling, role-playing, and positive reinforcement are helpful. Controlled studies suggest that schizophrenia patients are able to acquire lasting social skills after attending such programs and apply these skills to everyday life. Besides reducing anxiety, social skills training also improve level of social activity and foster new social contacts. This in turn improves the quality of life and significantly shortens duration of inpatient care. However, their impact on symptom resolution and relapse rates is unclear.

Cognitive Remediation

Patients with schizophrenia generally demonstrate poor performance in various aspects of information processing. Cognitive dysfunction can be a rate-limiting factor in learning and social functioning. Additionally, impaired information processing can lead to increased susceptibility to stress and thus to an increase risk of relapse. Practice appears to improve some of the cognitive dysfunction. Remediation of cognitive dysfunctions with social skills training has been reported to have positive impact. Mojtabai and colleagues (1998) performed a comprehensive metaanalysis of 106 controlled studies that were published between 1966 and 1994. They found that various types of cognitive behavioral therapies were particularly effective. Social skills training program, cognitive training program to improve neurocognitive functioning, and cognitive behavioral therapy approaches are oriented toward coping with symptoms, the disorder and everyday problems.

Cognitive Adaptation Training

Cognitive adaptation training (CAT) is a novel approach to improve adaptive functioning and compensate for the cognitive impairments associated with schizophrenia. A thorough functional needs assessment is done to measure current adaptive functioning. Besides measuring adaptive functioning and quantifying apathy and disinhibition, a neurocognitive assessment using tests to measure executive function, attention, verbal and visual memory, and visual organization is also completed. Treatment plans are adapted to the patient’s level of functioning, which includes patient’s level of apathy. Interventions include removal of distracting stimuli, use of reminders such as checklists, signs, and labels. In a randomized trial, 45 patients were randomized to a standard medication plus CAT group; standard medication follow-up group and a control group which included standard medication plus a condition designed to control for therapist time. At 9 months there was a significant improvement in positive and negative symptoms in the CAT group compared with the two other groups, namely follow-up group and control group of standard medication plus controlled therapist time. The most consistent improvement was in favor of CAT group and involved motivation as measured by rating instruments. The GAF scores also differed significantly between the groups. The relapse rates for CAT, control, and follow-up groups were significantly different (13.33, 67.67, and 33.33%, respectively).

Integrated Psychological Therapy (IPT)

IPT was one of the first clinically based cognitive rehabilitation programs that was specifically designed for persons
with schizophrenia. IPT is based on a building-block model that assumes that elementary, basic neurocognitive functions are necessary prerequisites for higher order complex social functions. Training is done in small groups in 30–60 mins sessions three times a week. There is training of abstraction, conceptual organization and basic perception and communication skills. The next level of training is behavioral level of social interaction and is similar to social skills discussed earlier. This is a structured, manual driven program for 6 months (Velligan et al. 2006).

Family Therapy

A large body of literature explores the role of familial interactions and the clinical course of schizophrenia. Many of these studies have examined the outcome of schizophrenia in relation to the degree of expressed emotion (EE) in family members. EE is generally defined as excessive criticism and over-involvement of relatives. Schizophrenia patients have been found to have a higher risk of relapse if their relatives have high EE levels. Clearly, a patient’s disturbing symptoms at the time of relapse may affect the level of criticism and over-involvement of family members, but evidence suggests that preexisting increased EE levels in relatives predict increased risk of schizophrenic relapse and that interventions that decrease EE levels can decrease relapse rates.

Specifically, studies have demonstrated effective strategies to lowering the risk of relapse with the use of family intervention and measurements of EE levels (Hogarty et al. 1986). For example, in a study by Falloon and colleagues (1985), 36 patients were randomly assigned to one of two treatment groups. One group received family therapy, the other individual therapy. In both groups the patients were maintained with appropriate antipsychotic doses. Family therapy was done in the home, with a focus on education about schizophrenia and ways in which families could achieve lowered stress levels and improved problem-solving skills. Specific problem-solving mechanisms were rehearsed and modeled by trained therapists. The individual treatment was supportive psychotherapy for the patient, which was conducted at the clinic. At the end of 9 months, family therapy was found to be a more effective means of preventing relapse (one relapsed out of 18) than individual therapy (eight relapsed out of 19). Moreover, the advantages of the family therapy persisted after a second year of less intensive follow-up (Falloon et al. 1985).

Hogarty and colleagues (1986) examined the effectiveness of antipsychotics alone, antipsychotics plus psychoeducational family treatment (based on addressing EE levels), social skills training for antipsychotic-treated patients with schizophrenia, and the combination of all three. Perhaps not surprisingly, they found a decreased relapse rate in the patients treated with medication and family therapy as well as in the group treated with antipsychotic and social skills training. The combination of the treatments had an additive effect and was far superior to medication treatment alone.

A controlled investigation of the effects of social intervention was also conducted. Patients were divided into groups, one that received routine outpatient treatment and one that underwent social intervention. In this study, one of the social interventions included reducing the time patients spent with their high-EE relatives. In addition, families received psychoeducational lectures about schizophrenia and its natural course and symptoms. Patients with schizophrenia received antipsychotics throughout the study. Relatives participated in group sessions that addressed coping mechanisms and familial interaction. As in the other studies, the patients who received the social interventions had a fivefold decrease in relapse rates that was sustained after 2-year follow-up.

Barbato and D’Avanzo (2000) critically reviewed family interventions in 25 randomized studies involving 1744 patients. Though the studies suffer from methodological limitations, the efficacy of family intervention on relapse rate is fairly well supported. This efficacy was particularly evident when contrasted with low quality or uncontrolled individual treatments. The addition of family intervention to standard treatment of schizophrenia has a positive impact on outcome to a moderate extent. Family intervention effectively reduces the short-term risk of clinical relapse after remission from an acute episode. There is evidence of effect on patient’s mental state and social functioning, or on any family-related variables. The elements common to most effective interventions are inclusion of the patient in at least some phases of the treatment, long duration, and information and education about the illness provided within a supportive framework. There are sufficient data only for male chronic patients living with high EE parents. Evidence is limited for recent-onset patients, women, and people in different family arrangements and families with low EE.

Research in family intervention is still a growing field. Thus, at present it is unclear if the effect seen with family therapy is due to family treatment or more intensive care.

Leff (2000) concluded from his review that family interventions reduced relapse rates by one-half over the first year of combined treatment with medications and family therapy. Medications and family therapy augment each other. Psychoeducation by itself is not enough. It also seems that multiple family groups are more efficacious than single family sessions. Attempts are being made to generalize training of mental health workers in effectively implementing these strategies. Pharoah et al. (2006) did a systematic review of literature involving 1765 participants and found that family intervention decreased the frequency of relapse, reduce hospital admission and may encourage compliance with treatment, it may prevent social impairment and the levels of expressed emotions.

Based on these findings, it is clear that there is a significant interaction between the level of emotional involvement and criticism of relatives of probands with schizophrenia and the outcome of their illness. Identifying the causative factors in familial stressors and educating involved family members about schizophrenia lead to long-term benefits for patients. Future work in this field must examine these interactions with an understanding of modern sociological and biological advances in genetics, looking at trait carriers, social skills assessments, positive and negative symptoms, and medication management with the SGAs.

Case Management

Assertive Community Treatment (ACT) is a community care model with a caseload per worker of 15 patients or less in contrast to standard case management (SCM) with
a caseload of 30 to 35 patients. Intensive clinical case management (ICCM) differs from ACT by the case manager not sharing the caseload. In the ACT model, most services are provided in the community rather than in the office; the caseloads are shared across clinicians rather than individual separate caseloads. These are time unlimited services provided directly by the ACT team and not brokered out and 24-hour coverage is provided. Research on the ACT model confirms that it is successful in making patients comply with treatment and leads to less inpatient admissions. ACT also improves housing conditions (fewer homeless patients, more patients in stable housing), employment, quality of life, and patient satisfaction. No clear differences between ACT and standard or intensive clinical case management are reported with mental condition, social functioning, self-esteem, or number of deaths.

Combining Pharmacological and Psychosocial Treatments
The combination of pharmacological and psychosocial interventions in schizophrenia can have complex interactions. For example, psychotherapies improve medication compliance on one hand but are more effective in the presence of antipsychotic treatment. Family psychoeducation has been reported to decrease the level of expressed emotion in the family resulting in better social adjustment and a need for lower dose of antipsychotic medications. Marder and colleagues, found in their study that pharmacological and psychosocial treatments affect different outcome dimensions. Medications affect relapse risk whereas skills training affect social adjustment. The VA cooperative study by Rosenheck and colleagues (2006), found that patients who received clozapine were more likely to participate in these treatments and led to improved quality of life. The qualitative differences in the interactions between the newer antipsychotic agents and psychotherapy suggest a hopeful trend of better utilization of psychosocial treatments.

Access to Psychosocial Treatments
Though significant advances have been made in psychosocial treatments, not everyone suffering from schizophrenia is able to access all of the different treatments they could benefit from. Urban areas often provide more choices than rural ones. Funding for psychosocial services is a chronic issue. Moreover, clinicians are often not likely to refer their patients under the mistaken belief that patients will not engage in therapy. While countries like UK are providing more home based services as they shut down mental hospitals, in USA, home-based treatments are not common.

Self-Directed Treatment
Groups such as the National Alliance for Mentally Ill (NAMI) and the Manic–Depressive Association offer tremendous resources to psychiatric patients and their relatives. They provide newsletters, neighborhood meetings, and support groups to interested persons. These nonprofessional self-help measures may feel less threatening to patients and their families and provide an important adjunct to professional settings.

Structured self-help clubs have also been effective means of bolstering patients’ social, occupational, and living skills. The Fountain House was the first such club aimed at social rehabilitation. Patients who are involved are called members of the club, giving them a sense of belonging to a group. They are always made to feel welcome, useful, and productive members of the club community.

The clubhouse model has expanded to provide services such as transitional employment programs, apartment programs, outreach programs, and medication management and consultation services, to name a few. A self-supportive rehabilitation program for mentally ill patients is an important option for many schizophrenia patients who might otherwise feel isolated and out of reach.

Stigma
Though tremendous progress has occurred in understanding and treatment of schizophrenia, stigmatizing attitudes still prevail; in a survey, schizophrenia elicited the most negative opinions and over 70% of those questioned thought that schizophrenia patients were dangerous and unpredictable. Thus, stigma surrounding schizophrenia can cause people suffering from the illness to develop low self-esteem, disrupt personal relationships, and decrease employment opportunities. The World Psychiatric Association (WPA), has initiated an international program aimed at developing tools to fight stigma and discrimination.

Clinical Vignette 1
Mr. A first sought psychiatric help at the age of 19 years. During his first year of college he had a difficult adjustment. He had never had close friends, but at school he felt isolated from his family. Although he had always been a good student, averaging As and Bs in high school, he was unable to achieve the same level of academic performance. He became increasingly distressed by his sense of isolation and his inability to maintain an adequate grade point average. Around the middle of his first year of college he saw a psychiatrist, who thought he was having an adjustment reaction to his new surroundings. He was not given medication at the time but was referred for supportive psychotherapy. After two appointments with his therapist, he decided it was not helpful.

Shortly thereafter, he began to feel that the other students were staring at him and laughing at him behind his back. Then he began to feel as if they were playing tricks on him, sending secret messages to him over the radio to torment him. This experience lasted over 6 months. He also began hearing two voices, which he did not recognize. These voices would comment on his behavior and criticize his actions. They began to tell him to stay out of his dormitory room at night. The voices also warned him that the dormitory food was poisoned. One night, he was picked up by police for loitering and was brought to an emergency department.

The emergency department psychiatrist saw him as a disheveled, unshaven man who was agitated during the interview, pacing across the examining room. He was wearing dark sunglasses, although it was the middle of the night, and he said he did not want the examiner to read his mind by looking into his eyes, so he kept the sunglasses on throughout the interview. His speech was of normal rate and prosody, although there were long pauses in some of his responses. He was able to respond to questions clearly, and his thought processes were logical, although he
repeatedly spoke angrily as if responding to voices. He did say that the voices had been telling him to kill himself for the past two nights, although he said he was trying not to listen to them. The patient showed only some difficulty in concentration on a cognitive examination. His judgment was fair in that he recognized his need for some help, but he showed no insight into his symptoms.

The psychiatrist felt that the patient was potentially a risk of harm to himself because of the command auditory hallucinations and required hospitalization. Mr. A did not agree to come into the hospital, and the psychiatrist sought involuntary hospitalization through appropriate procedures. In the hospital, the patient was initially quite agitated, requiring intramuscular haloperidol and lorazepam. Almost immediately his behavior calmed, and he was able to agree to hospitalization and treatment. He was treated with risperidone, and the dose was titrated up to 3 mg/day by mouth at bedtime. After 1 week with this medication regimen, he began to experience a decrease in his auditory hallucinations and paranoid ideation. He was sleeping better and was no longer concerned about the foods he was eating.

Almost immediately his behavior calmed, and he was able to agree to hospitalization and treatment. He was treated with risperidone, and the dose was titrated up to 3 mg/day by mouth at bedtime. After 1 week with this medication regimen, he began to experience a decrease in his auditory hallucinations and paranoid ideation. He was sleeping better and was no longer concerned about the foods he was eating.
symptoms” during the same period of illness. The mood disorder symptoms must be present for a substantial part of the active and residual psychotic period. The essential features of schizoaffective disorder must occur within a single uninterrupted period of illness where the “period of illness” refers to the period of active or residual symptoms of psychotic illness and this can last for years and decades. The total duration of psychotic symptoms must be at least 1 month to meet the criteria A for schizophrenia and thus, the minimum duration of a schizoaffective episode is also 1 month.

The criteria for major depressive episode require a minimum duration of 2 weeks of either depressed mood or markedly diminished interest or pleasure. As the symptoms of loss of pleasure or interest commonly occur in nonaffective psychotic disorders, to meet the criteria for schizoaffective disorder criteria A, the major depressive episode must include pervasive depressed mood. Presence of markedly diminished interest or pleasure is not sufficient to make a diagnosis as it is possible that these symptoms may occur with other conditions too.

The DSM-IV-TR diagnosis of schizoaffective disorder can be further classified as schizoaffective disorder bipolar type or schizoaffective disorder depressive type. For a person to be classified as having the bipolar subtype he/she must have a disorder that includes a manic or mixed episode with or without a history of major depressive episodes. Otherwise, the person is classified as having depressive subtype having had symptoms that meet the criteria for a major depressive episode with no history of having had mania or mixed state.

Clinical Features
The clinical signs and symptoms of schizoaffective disorder include all the signs and symptoms of schizophrenia, and a manic episode and/or a major depressive episode. The schizophrenia and mood symptoms may occur together or in an alternate sequence. The clinical course can vary from one of exacerbations and remissions to that of a long-term deterioration. Presence of mood-incongruent psychotic features—where the psychotic content of hallucinations or delusions is not consistent with the prevailing mood—more likely indicate a poor prognosis.

Epidemiology
As discussed earlier, the diagnosis of schizoaffective disorder has undergone numerous changes through the decades making it difficult to get reliable epidemiology information. When data were pooled together from various clinical studies, approximately 2-29% of those patients diagnosed to have mental illness at the time of the study were suffering from schizoaffective disorder with women having a higher prevalence. This could possibly be explained by a higher rate of depression in women. Relatives of women suffering from schizoaffective disorder have a higher rate of schizophrenia and depressive disorders compared to relatives of male schizoaffective subjects. The estimated lifetime prevalence of schizoaffective disorder based on an elegant study done recently by Perala et al. (2007) is 0.32% (95% CI = 0.21–0.46) with men having 0.14% (95% CI = 0.06–0.34) which was statistically significantly different compared to women at 0.47% (95% CI = 0.30–0.72). In the inpatient settings of New York State psychiatric hospitals, approximately 19% of 6,000 patients had a diagnosis of schizoaffective disorder.

Gender and Age
The depressive type of schizoaffective disorder appears to be more common in older people while the bipolar type probably occurs more commonly in younger adults. The higher prevalence of the disorder in women appears to occur particularly amongst those who are married. As in schizophrenia, the age of onset for women is later than that for men. Depression tends to occur more commonly in women.

Course and Prognosis
Regarding the prognosis of schizoaffective disorder, to the extent that this illness has symptoms from both a major mood disorder and schizophrenia, theoretically one can confer a relatively better prognosis than schizophrenia and a relatively poorer prognosis than bipolar disorder. In one study where DSM-III and DSM-IV patients with schizoaffective disorder were followed for 8 years, the outcome of these patients more closely resembled schizophrenia than mood disorder with psychosis. Some data indicate that patients with a diagnosis of schizoaffective disorder bipolar type have a 2-5 years course similar to that of bipolar disorder, while patients diagnosed to have schizoaffective disorder depressive type have a course similar to schizophrenia on outcome measures such as occupational and social functioning after the index episode (Grossman et al. 1991). Regardless of the subtype, the following variables are harbingers of a poor prognosis:

1. a. poor premorbid history
2. b. an insidious onset
3. c. absence of precipitating factors
4. d. a predominance of psychotic symptoms, especially deficit or negative ones
5. e. an early age of onset
6. f. an unremitting course, and
7. g. a family history of schizophrenia.

The corollary would be that the opposite of each of these characteristics would suggest a better prognosis. Interestingly, the presence or the absence of Schneiderian first-rank symptoms does not seem to predict the course of illness. The incidence of suicide in patients with schizoaffective disorder is at least 10%. Some data indicate that the suicidal behavior may be more common in women than men.

In a small sample comparing 27 schizoaffective disorder with 27 bipolar disorder patients, first-rank symptoms and mood-incongruent psychosis did not differ between the two groups. Over 70% of the sample included unemployed or unskilled laborers. A few studies have reported that low socioeconomic status is a strong predictor of poor outcome.

In one study, 82% of those patients who were suffering from a first episode of schizoaffective disorder and had recovered, experienced psychotic relapse within 5 years. These patients had high rates of second and third relapses despite careful monitoring. Medication discontinuations in first episode patients who are stable for 1 year substantially increase relapse risks. Aside from medication status, premorbid social
adjustment was the only predictor of relapse in their study. Poor adaptation to school and premorbid social isolation predicted initial relapse independent of medication status. Thus, like schizophrenia, the risk of relapse is diminished by antipsychotic maintenance treatment.

**Differential Diagnosis**
The possible differential diagnosis consists of bipolar disorder with psychotic features, major depressive disorder with psychotic features, and schizophrenia. Clearly, substance induced states and symptoms caused by coexisting medical conditions should be carefully ruled out. All conditions listed in differential diagnosis of schizophrenia, bipolar disorder, and major depressive disorder should be considered including but not limited to those patients undergoing treatment with steroids, those abusing substances such as PCP and medical conditions such as temporal lobe epilepsy. In circumstances where there is ambiguity, it may be prudent to delay making a final diagnosis until the most acute symptoms of psychosis have subsided and time is allowed to establish a course of illness and collect collateral information.

**Etiology**
The etiology of schizoaffective disorder is unknown. There is a dearth of data relating to this illness. Studies involving families of schizoaffective probands suggest that they have significantly higher rates of relatives with mood disorder than families of schizophrenia probands. It is possible that some of the same environmental theories that apply to schizophrenia and bipolar disorder may also apply to schizoaffective disorder. Recent linkage studies have implicated the DISC1 gene locus for schizoaffective disorder.

Over the years, the concept of schizoaffective disorder has evolved such that many view it as either a type of schizophrenia or a type of mood disorder. Some have suggested that schizoaffective disorder represents a variant of schizophrenia in terms of clinical symptoms, family history and treatment. Moreover, in some studies schizophrenia patients did not differ from schizoaffective ones on cognitive impairment. Williams and associates suggested that the disorder represents a variant of schizophrenia or mood disorder while others consider it to be on a continuum of illness intermediate between schizophrenia or mood disorder. One opinion is that schizoaffective disorder represents a phenotypic variation of either schizophrenia or mood disorder and over the long term becomes a subtype of either one. Alternatively, some view schizoaffective disorder as the simultaneous expression of schizophrenia and a mood disorder. However, Kendler and colleagues observe that schizoaffective patients differ significantly from both schizophrenia and mood disorder patients. Specifically, schizoaffective patients have more affective symptoms, fewer negative symptoms and a better course and outcome than schizophrenia. Bertelsen and Gottesman (1995) reviewed the literature relevant to genetic predisposition to schizoaffective disorder. Though variable, the results generally suggest that schizoaffective disorder is either a phenotypic variation or an expression of a genetic interform between schizophrenia and mood disorder, a position similar to Kendler. However, the possibility that schizoaffective disorder is distinct from schizophrenia and mood disorders is not supported by the observations that only a small percentage of the relatives of schizoaffective disorder probands have schizoaffective disorder.

It is most likely that schizoaffective disorder is a heterogeneous condition that includes all of the possibilities mentioned above. Thus, depending on the type of schizoaffective disorder studied an increased prevalence of either schizophrenia or mood disorders may be found in their relatives. As a group, patients with schizoaffective disorder have a prognosis intermediate between mood disorders and schizophrenia. Thus, on an average they have a better course than those suffering from schizophrenia, respond to mood stabilizers more often and tend to have a relatively nondeteriorating course.

**Treatment**
With the shifting definitions of schizoaffective disorder, evaluating the treatment of schizoaffective disorder is not easy. Mood stabilizers, antidepressants, and antipsychotic medications clearly have a role in management of these patients. The presenting symptoms, their duration and intensity, and patient choices need to be incorporated into deciding what treatment(s) to choose.

**Antipsychotic Medications**
Second Generation Antipsychotic medications (SGA) are reported to be more effective than the First Generation ones (FGA) in the treatment of schizoaffective disorder. They appear to have more broad-spectrum effects than the FGAs. Optimizing antipsychotic treatment, especially with the SGAs is more likely to be effective than the routine use of adjunctive antidepressants or mood stabilizers. However, when indicated, the use of antidepressants is well supported in schizoaffective patients who present with a full depressive syndrome after stabilization of psychosis.

Olanzapine is effective against symptoms of psychosis, mania, and depression. Tollefsen and colleagues studied 300 patients with schizoaffective disorder bipolar type, one of the largest studies of its kind in schizoaffective disorder, and reported that olanzapine was significantly superior to haloperidol in treating affective and psychotic symptoms.

Ziprasidone was studied in 115 hospitalized patients with acute episode of schizoaffective disorder using a double blind randomized design. Ziprasidone was significantly superior to placebo and was well tolerated (Keck et al. 2001). Ziprasidone also has significant antidepressant effects at doses of 120 to 160 mg/day.

Vieta and colleagues studied 102 schizoaffective disorder bipolar type patients where risperidone was added to their existing regimen of mood stabilizers in the absence of an antipsychotic agent. Risperidone had significant clinical efficacy and a favorable safety profile when combined with mood stabilizers in patients with schizoaffective disorders. The response rate was comparatively better than what is typically observed in schizophrenia studies. Hillert and associates also reported that treatment with risperidone reduced both psychotic and mood symptoms in patients with schizoaffective disorder depressed type. However, a study with a small sample, did not find significant differences between haloperidol and risperidone in a
short-term 6-week double-blind randomized study. However, risperidone proved significantly greater responders in the patients with severe depression and also improved the sleep factor. Moreover, risperidone did not exacerbate manic symptoms, a prevailing concern at the time when this study was conducted. Furthermore, the risperidone group had less EPS compared to haloperidol. Efficacy of clozapine in schizoaffective disorder has been reported in several short term studies or chart reviews. Clozapine monotherapy has been reported to be effective in treatment up to 16 months in a small sample. Presence of affective symptoms predicted good response to clozapine. When clozapine use was compared in treatment refractory schizophrenia, bipolar disorder, and schizoaffective disorder the outcomes were significantly better in bipolar disorder and schizoaffective disorder. Persistent and enduring improvements with clozapine lasting 1 to 2 years have been reported. Clozapine also helps decrease suicidality. Thus, clozapine use may be beneficial in treatment refractory schizoaffective disorder as it has both mood stabilizing and antipsychotic properties, a substantial advantage.

Mood Stabilizers
Two small open label studies suggest that valproic acid is effective in treating the manic symptoms associated with schizoaffective disorder, bipolar type with 65.2% reduction in manic episodes in 5 patients after 29 to 51 months. Similar results were reported by another study where 79% of the patients reported improvement after 1-year treatment with valproic acid. A study with small sample also reported 75% improvement in Clinical Global Impression scale.

Three double-blind, parallel-group studies examined the efficacy of lithium carbonate in schizoaffective mania. One study found that chlorpromazine alone was as effective as the combination of chlorpromazine and lithium. Another study, with a small sample found that the combination of lithium and haloperidol was more effective than haloperidol itself in patients with predominantly affective symptoms compared to those with predominantly psychotic symptoms. Reports of carbamazepine use are sparse and difficult to draw conclusions from. Lamotrigine was also reported to be useful in 3 cases of schizoaffective disorder. A comprehensive review by Cochrane Group has reported that concomitant use of lithium with antipsychotics was particularly efficacious in schizoaffective group.

Antidepressants. The SGAs are often efficacious against depression in patients who suffer from both depression and psychosis negating the need for routine use of antidepressants. However, there are patients who remain depressed even with optimal antipsychotic and mood stabilizer treatment. SSRIs are widely used in patients who present with schizoaffective disorder with depression. If the SSRIs and newer antidepressants do not show efficacy, tricyclic antidepressants do have a role. Interestingly, chlorpromazine in combination with amitriptyline was reported to be as effective as chlorpromazine alone. Many studies suggest that addition of antidepressants helps in effective treatment of depression in schizoaffective disorder. Occasionally, antidepressants may worsen the course. For patients suffering from depression where they are not responding adequately and are at risk for suicide, ECT is an effective alternative.

Psychosocial Treatment. To the extent that schizoaffective disorder shares symptoms with schizophrenia, most of the psychosocial treatments used in the treatment of schizophrenia are likely to be useful in the treatment of schizoaffective disorder. Specifically, patients benefit from individual supportive therapy, family therapy, group therapy, cognitive–behavioral therapy, and social skills training. Many patients would be suitable candidates for assertive community therapy (ACT). Depending on the level of recovery, some of the patients may need rehabilitation services to assist them with either developing skills for some form of employment or assistance to maintain a job. Family members benefit from support groups such as NAMI or MDA groups.

Clinical Vignette 3
Ms. Jones is a 29-year-old married woman with two children. She reported having problems with her sleep 9 months after the birth of her second child as marking the beginning of her illness. She was erratic, irritable, and gradually declined in her functioning. Her family noticed that she was unable to care for herself and her children. She was paranoid, suspicious of her neighbors, and felt that they were spying on her. She isolated herself in the house. Soon she was also noted to have euphoric mood with racing thoughts and grandiose delusions of being a very powerful person endowed with gifts from god. She was barely sleeping, only a few hours a day. After approximately 6 weeks of this behavior, she was brought to hospital after she got into a verbal altercation with her neighbor. There was no history of any medical problems, medication use, or any drug abuse. She was admitted to the hospital, started on valproic acid, and the dose was titrated up to 1,500 mg/day with blood levels of 80. Her symptoms of mania resolved within 2 weeks and she was discharged. However, on the follow-up visit, she reported being suspicious of her neighbor and felt that she was being watched. Her husband reported that patient kept the shades down on the side where the neighbors lived. She was started on ziprasidone 20 mg (QIe interval within normal range) twice a day and the dose was increased to 120 mg/day. Her symptoms resolved completely at the next visit. One year later, she was doing well on monotherapy of ziprasidone 120 mg/day and had started working part time.

Brief Psychotic Disorder

Diagnosis
Brief psychotic disorder is defined by DSM-IV-TR as a psychotic disorder that lasts more than 1 day and less than a month. Moreover, the disorder may develop in response to severe psychosocial stressors or group of stressors.

European and Scandinavian countries have traditionally diagnosed this type of psychosis as psychogenic psychoses, reactive psychosis, or brief reactive psychosis. Some have also referred to this condition as hysterical psychosis. These terms are probably more commonly used in Scandinavian countries due to Langfeldt and Leonhard's contributions to the classification of psychosis that does not have a course
like schizophrenia. In the US, brief reactive psychosis was formally included as a diagnostic category in DSM-III. Subsequently it has undergone a change in its name to brief psychotic disorder.

The DSM-IV-TR diagnostic criteria specify the presence of at least one clear psychotic symptom lasting a minimum of 1 day to a maximum of 1 month. Furthermore, DSM-IV-TR allows the specification of two additional features: the presence or the absence of one or more marked stressors and a postpartum onset starting within four weeks of postpartum period. DSM-IV-TR describes a continuum of diagnosis for psychotic disorder based primarily on duration of the symptoms. Once the duration criteria are met, other conditions such as etiological medical illnesses and substance-induced psychosis need to be excluded. In those cases where the duration of psychosis lasts more than 1 month, appropriate diagnosis to be considered are other psychotic conditions based on reevaluation of the clinical features, duration of psychosis, and presence of mood symptoms.

Clinical Features
People suffering from this disorder usually present with an acute onset, manifest at least one major symptom of psychosis, and do not always include the entire symptom constellation seen in schizophrenia. Affective symptoms, confusion, and impaired attention may be more common in brief psychotic disorders than in chronic psychotic conditions. Some of the characteristic symptoms include emotional lability, outlandish behavior, screaming or muteness, and impaired memory for recent events. Some of the symptoms suggest a diagnosis of delirium and may warrant a more complete medical workup. The symptom patterns include acute paranoid reactions, reactive confusions, excitations, and depressions. In French psychiatry, Bouffee delirante is similar to brief psychotic disorder.

Epidemiology
This illness is not uncommon, but, unfortunately, reliable estimates of the incidence, prevalence, sex ratio, and average age of onset are not available. Recently, using well-defined measures in a nationally representative sample of 8028 subjects 30 years or older, Lifetime Prevalence was estimated at 0.05% (95% CI = 0.02–0.14) with rates in men were 0.08% (95% CI = 0.03–0.26) and in women 0.02% (95% CI = 0.00–0.17) making this a rare disorder (Peral et al. 2007). It is believed that this disorder is more common among young people with occasional cases involving older people. This disorder may be seen more commonly in patients from low socioeconomic classes and in those with personality disorders such as histrionic, paranoid, schizotypal, narcissistic, and borderline. Though immigrants and people who have experienced major disasters are reported to be at a higher risk, well-controlled studies have failed to show this.

Precipitating Stressors
The precipitating stressors most commonly encountered are major life events that would cause any person significant emotional turmoil. Such events include the death of a close family member or severe accidents. Rarely, it could be accumulation of many smaller stresses.

Course and Prognosis
As defined by DSM-IV-TR, the duration of the disorder is less than 1 month. Nonetheless, the development of such a significant psychiatric disorder may indicate a patient’s mental vulnerability. An unknown percentage of patients who are first classified as having brief psychotic disorder later display chronic psychiatric syndromes such as schizophrenia and bipolar disorder. Patients with brief psychotic disorders generally have good prognosis, and European studies indicate that 50 to 80% of all patients have no further major psychiatric problems.

The length of the acute and residual symptoms is often just a few days. Occasionally, depressive symptoms follow the resolution of the psychosis. Suicide is a concern during both the psychotic phase and the postpsychotic depressive phase. Indicators of good prognosis are good premorbid adjustment, few premorbid schizoid traits, severe precipitating stressors, sudden onset of symptoms, confusion and perplexity during psychosis, little affective blunting, short duration of symptoms, and absence of family history of schizophrenia.

Differential Diagnosis
Although the classical presentation may be short in duration and associated with stressors, a thorough and careful evaluation is necessary. Additional information is critical to rule out other major psychotic conditions as temporal association of stressors to the acute manifestation of symptoms may be coincidental and thus misleading. Other conditions to be ruled out include psychotic disorder due to a general medical condition, substance-induced psychosis, factitious disorder with predominantly psychological signs and symptoms, and malingering. Patients with epilepsy and delirium may also present with similar symptoms. Additional conditions to be considered are dissociative identity disorder and psychotic episodes associated with borderline and schizotypal personality disorder that may last for less than a day.

Etiology
As with other psychotic illnesses, this condition appears to be heterogeneous; clearly, more research is necessary. The development of psychosis is an important indication of severity of this illness and may suggest either a breakdown of or inadequate coping mechanisms.

Treatment
These patients may require short-term hospitalizations for a comprehensive evaluation and safety. Antipsychotic drugs are often most useful along with benzodiazepines. Long-term use of medication is often not necessary and should be avoided. If maintenance medications are necessary, the diagnoses may need to be revised. Clearly, the newer antipsychotic agents have a better neurological side effect profile and would be preferred over the typical agents.

Psychotherapy is necessary to help the person reintegrate the experience of psychosis and possibly the precipitating trauma. Individual, family, and group therapies may be necessary in some individuals. Many patients need help to cope with the loss of self-esteem and confidence.
Clinical Vignette 4

A 35-year-old recently separated immigrant woman was brought to the emergency room in an acutely agitated state with auditory hallucinations and confusion. She immigrated to the US 2 years ago to join her husband of 5 years. They separated 3 months ago; she lost her job a month later and had to bear significant financial hardship. Her father was medically ill and passed away unexpectedly 6 weeks previously. According to people close to her, she started having symptoms approximately 7 days before her admission. She was reported to be restless, pacing, and preoccupied with the recent stressors. On various occasions, her speech was tangential or incoherent. Her mood was labile and she appeared to be perplexed at times. Her attention and concentration was poor. She was paranoid of her husband (family members denied him being a threat to her) and often felt that her deceased father was communicating with her. She had passive suicidal thoughts. She was often upset about being hospitalized and demanded release from the hospital. She would get quite angry and throw tantrums if her request for discharge was denied. There was no history of alcohol or drug use. She was in good physical health. There was no history of similar or other episodes.

Admission work up was essentially normal. The urine toxicology screen, pregnancy test, and EEG were normal. Following admission, she was started on a low dose of benzodiazepine and an atypical antipsychotic agent. Her symptoms of agitation and psychosis responded rapidly within 1 week. Individual and group therapy sessions were very helpful in addressing her recent stressors and providing emotional support. Family therapy was offered but the patient and her family rejected it. With the help of individual and group therapy, she was able to develop some coping skills. Following discharge, she continued to respond to the low dose antipsychotic treatment and other therapies. She was not having any symptoms of psychosis and was able to deal with her stressors better. Approximately 3 weeks after discharge, though her stressors continued, she was responding well to the treatment, reached her baseline functioning, but due to significant weight gain and sedation, she decided to discontinue her medication. Six months later, she has continued with psychotherapy and group therapy, and has maintained her baseline functioning.

Schizophreniform Disorder

Diagnosis

Gabriel Langfeldt (1939) suggested the term Schizophreniform Disorder in 1937 for a heterogeneous group of patients characterized by the similarity of their symptoms to those of schizophrenia albeit with a good clinical outcome. Langfeldt observed that those patients whose diagnosis was questionable as schizophrenia had a much better outcome than those whose diagnosis was confirmed as schizophrenia; these patients were thus classified as having schizophreniform psychosis. Langfeldt also noted that these patients often had good premorbid adjustment, an abrupt onset of symptoms, frequent presence of psychosocial stressor(s), and a good prognosis.

Schizophreniform disorder shares a majority of the DSM-IV-TR diagnostic features with schizophrenia (see diagnostic criteria on page xxx) except the following two criteria: (a) the total duration of the illness which includes the prodrome, active, and residual phases is at least 1 month but less than 6 months in duration; (b) though impairment in social and occupational functioning may occur during the illness, it is not required or necessary. Thus, the duration of more than 1 month eliminates brief psychotic disorder as a possible diagnosis; if the illness lasts or has lasted for more than 6 months, the diagnosis has to be reevaluated for other possible conditions including schizophrenia. Therefore, the diagnosis of schizophreniform disorder is intermediate between brief psychotic disorder and schizophrenia. Hence, those patients whose duration of episode lasted more than a month and less than 6 months, and have recovered would be diagnosed as having schizophreniform disorder. On the other hand those patients who have not recovered from an episode, which is less than 6 months but more than 1 month in duration, and are likely to have schizophrenia would be diagnosed to have schizophreniform disorder until the 6 months criteria is met for schizophrenia. The diagnosis of ‘provisional’ schizophreniform disorder is made while the clinician monitors the evolving course of the illness, waits for the symptoms to resolve, or when the clinician cannot obtain a reliable history from a patient about the duration of the symptoms.

Specifiers for Prognostic Features

The DSM-IV-TR has specifiers for the presence or absence of good prognostic features. These features include a rapid onset (within four weeks) of prominent psychotic symptoms, presence of (psychogenic) confusion or perplexity at the height of the psychotic episode, good premorbid adjustment as evidenced by social and occupational functioning, and the absence of deficit symptoms such as blunted or flat affect.

Clinical Features

The clinical signs and symptoms and the Mental Status Examination of the patient with schizophreniform disorder are often similar to those with schizophrenia, but the presence of affective symptoms usually predict a favorable course. Alternatively, a flat or blunted affect may predict an unfavorable course.

Epidemiology

Little is known about the incidence, prevalence, and sex ratio of schizophreniform disorder (Poulton et al. 2000). A strong linear relationship has been reported between self-reported psychotic symptoms in childhood at age 11 years and subsequent development of adult schizophreniform disorder. Those children with strong symptoms were 16 times more likely to have a schizophreniform diagnosis by age 26 years compared to control group. Forty-two percent of those who developed schizophreniform psychosis by age 26 years in the cohort had reported 1 or more psychotic symptoms at age 11 years. Interestingly, these psychotic symptoms which appeared at age 11 years did not predict mania or depression at age 26 years (Poulton et al. 2000). Over the years, schizophreniform psychosis has moved much closer to the diagnosis of schizophrenia. ECA studies indicate prevalence of 0.2% lifetime prevalence and 1-year prevalence of 0.1%. A well designed, elegant population survey of nationally representative sample of 8,028 subjects reported lifetime
Family History
Several studies suggest that the relatives of patients with schizophreniform psychosis are at a high risk of having psychiatric disorders. The relatives of patients with schizophreniform psychosis are more likely to have mood disorders than are the relatives of patients with schizophrenia. In addition, the relatives of patients with schizophreniform disorder are more likely to have a diagnosis of a psychotic mood disorder than are the relatives of patients with bipolar disorders.

Course and Prognosis
This is, as anticipated, variable. The DSM IV-TR specifies “with good prognostic features” and “without good prognostic features” though helpful in guiding the clinician, require further validation. However, confusion or perplexity at the height of the psychotic episode is the feature best correlated with good outcome. Also, the shorter the period of illness, the better the prognosis is likely to be. There is a significant risk of suicide in these patients. Postpsychotic depression is quite likely and should be addressed in psychotherapy. Psychotherapy may help speed the recovery and improve the prognosis. By definition, schizophreniform disorder resolves within 6 months with a return to baseline mental functioning. With increased focus on first episode psychosis and early intervention, more studies will provide data regarding stability of diagnosis and longitudinal course. Those individuals who went on to develop schizophrenia had poorer premorbid functioning and longer duration of untreated psychosis, compared to those who did not.

Differential Diagnosis
This is similar to schizophrenia. Psychotic disorder caused by a general medical condition and substance-induced psychotic disorder must be ruled out. General medical conditions to be considered are HIV infection, temporal lobe epilepsy, CNS tumors, and cerebrovascular disease, all of which can also be associated with relatively short-lived psychotic episodes. The increasing number of reports of psychosis associated with the use of anabolic steroids by young men who are attempting to build up their muscles to perform better in athletic activities require careful history. Factitious disorder with predominantly psychological signs and symptoms and malingering may need to be ruled out in some instances.

Etiology
Schizophreniform psychosis, similar to other psychosis, is probably heterogeneous and due to an unknown cause. In general, some patients have a disorder similar to schizophrenia, whereas others have a disorder similar to mood disorders. Some data, however, indicate a close relation to schizophrenia. Several studies have shown that patients with schizophreniform disorder, as a group, have more affective symptoms (especially mania) and a better outcome than do patients with schizophrenia. In addition, the increased presence of mood disorders in the relatives of patients with schizophreniform disorder indicates a relation to mood disorders. Thus, the biological and epidemiological data are most consistent with the hypothesis that the current diagnostic category defines a group of patients, some of whom have a disorder similar to schizophrenia and others similar to a mood disorder.

Brain Imaging
As in schizophrenia, a relative activation deficit in the inferior prefrontal region of the brain while the patient is performing Wisconsin Card Sorting Test is reported. One study showed that the deficit was limited to the left hemisphere indicating a similarity to schizophrenia. More studies are needed to determine the long-term course which is often variable and sometimes similar to schizophrenia but more often a shortened course quite different from schizophrenia. Some data indicate that patients with schizophreniform disorder may have enlarged ventricles, as seen on CT scans and MRI, while other data indicate that unlike the enlargement seen in schizophrenia, the ventricular enlargement in schizophreniform disorder is not correlated with outcome measures or other biological measures.

Other Biological Measures
Although brain-imaging studies suggest a similarity between schizophreniform disorder and schizophrenia, one study of electrodermal activity has indicated a difference. Patients with schizophrenia born during the winter and spring months had hypoactive skin conductances, but this association was absent in patients with schizophreniform disorder. Though the significance of this one study would be difficult to interpret, the results do suggest caution in assuming similarity between patients with schizophrenia and those with schizophreniform disorder. Data from a study of eye tracking in the two groups also indicate that there are differences on some biological measures between schizophrenia and schizophreniform psychosis.

Treatment
Hospitalization is often necessary and allows for effective assessment, treatment, and supervision of a patient’s behavior. The psychotic symptoms, usually treated with a 3- to 6-month course of antipsychotic drugs, respond more rapidly than in patients with schizophrenia. One study found that 75% of the patients with schizophreniform psychosis compared to 20% of those with schizophrenia responded to antipsychotic agents within 8 days. ECT may be indicated for some patients, especially those with marked catatonic features or depression. If a patient has recurrent episodes, trials of lithium carbonate, valproic acid, or carbamazepine may be warranted for prophylaxis. Psychotherapy is usually necessary to help patients integrate the psychotic experience into their understanding of their minds, brains, and lives.

Clinical Vignette 5
Mr. A is a 25-year-old married white male who was brought to the emergency room by his family with complaints of paranoid thinking, agitation, auditory hallucinations, and insomnia. His family noticed that he was anxious, withdrawn, and had difficulty sleeping through the night 6 weeks previously. He reported to his wife that he was being harassed by his coworkers and felt that they were plotting against him. Mr. A reported hearing voices (continues)
Delusional disorder refers to a group of disorders, the chief feature of which is the presence of nonbizarre delusions. People suffering from this illness do not regard themselves as mentally ill and actively oppose psychiatric referral. Because they may experience little impairment, they generally remain outside hospital settings, appearing reflective, eccentric, or odd, rather than ill. They are more likely to have contacts with professionals such as lawyers and other medical specialists for health concerns. The current shift in diagnosis from paranoid to delusional helps avoid the ambiguity around the term ‘paranoid.’ This also emphasizes that other delusions besides the paranoid ones are included in this diagnosis. It is important to understand the definition of nonbizarre delusion so as to reach an unambiguous diagnosis. Nonbizarre delusions typically involve situations or circumstances that can occur in real life (e.g., being followed, infected, or deceived by a lover) and are believable.

History
The classical description of paranoia by Karl Ludwig Kahlbaum in 1863 paved the way for classification of paranoia. Kraepelin struggled with the concept of paranoia and his thinking finally evolved to define paranoia as an uncommon, insidious, chronic illness characterized by a fixed delusional system, an absence of hallucination, and a lack of deterioration of personality. Bleuler, on the other hand, viewed paranoia as a rare and milder version of schizophrenia and was not comfortable with a separate diagnosis. Freud used the autobiography of Daniel Paul Schreber, a jurist, and interpreted how unconscious homosexual tendencies were defended against by denial and projection in the form of delusions of persecution. His case study laid the basis for the psychodynamic understanding of paranoia.

Diagnostic Criteria
According to DSM-IV-TR, the diagnosis of delusional disorder can be made when a person exhibits nonbizarre delusions of at least 1 month duration that cannot be attributed to other psychiatric disorders. Nonbizarre delusions must be about phenomena that, although not real, are within the realm of being possible. In general, the patient’s delusions are well systematized and have been logically developed. If the person experiences auditory or visual hallucinations, they are not prominent except for tactile or olfactory hallucinations where they are tied in to the delusion (e.g., a person who believes that he emits a foul odor might experience an olfactory hallucination of that odor). The person’s behavioral and emotional responses to the delusions appear to be appropriate. Usually the person’s functioning and personality are well preserved and show minimal deterioration if at all.

Subtypes
Persecutory Type
This is the most common form of delusional disorder (Yamada et al. 1998). Here the person affected believes that he or she is being followed, spied on, poisoned or drugged, harassed, or conspired against. The person affected may get preoccupied by small slights that can become incorporated into the delusional system. These individuals may resort to legal actions to remedy perceived injustice. Individuals suffering from these delusions often become resentful and angry with a potential to get violent against those believed to be against them.

Jealous Type
Individuals with this subtype have the delusional belief that their spouses/lovers are unfaithful. This is often wrongly inferred from small bits of benign evidence which is used to justify the delusion. Delusions of infidelity have also been called conjugal paranoia. The term Othello syndrome has been used to describe morbid jealousy. This delusion usually affects men, with no history of prior psychiatric problems. The condition is difficult to treat and may diminish only on separation, divorce, or death of the spouse. Marked jealousy (pathological jealousy or morbid jealousy) is a symptom of many disorders including schizophrenia and not unique to delusional disorder. Jealousy is a powerful emotion and when it occurs in delusional disorder or as part of another condition, it can be potentially dangerous and has been associated with violence including suicidal and homicidal behavior.

Erotomanic Type
Persons with delusional disorder of the erotomanic type have delusions of being loved by another. Most frequently, the patient is a woman, though men are also susceptible to these delusions. The patient believes that a perceived suitor, usually more socially prominent than herself, is in...
love with her. This can become central focus of the patient’s existence and the onset can be sudden. Erotomania shares many features with, is derived from, and is often referred to as de Clerambault’s syndrome. Erotomanic delusions are not unique to delusional disorder, and can occur as part of other disorders too. Persons with erotomanic delusions often exhibit what has been called paradoxical conduct, the delusional phenomenon of interpreting all denials of love no matter how clear as secret affirmations of love. At times, it can manifest with more aggressive and possibly violent pursuit of love. Though the data are varied, one author has suggested that approximately 10% of stalkers have a primary diagnosis of erotomania. Recent data support that though they are less likely to be violent than other stalker types, stalkers with erotomanic delusions can become violent (Resnick 2007). Thus, such people are often in a forensic system. In a review by Meloy (1996), if violence occurred the object of love was the target at least 80% of the time, often related to resentment and rage in response to an absence of reaction from all forms of love communication or perceived jealousy. However, the object of aggression may also be companions or protectors of the love object who are viewed as trying to come between the lovers. Approaches to management can be difficult, as criminal sanctions alone may be inadequate. A combination of judicial interventions, and possible separation of victim and the person who are viewed as trying to come between the lovers, may be needed in concert.

**Somatic Type**

Delusional disorder with somatic delusions has been called monosymptomatic hypochondriacal psychosis. This disorder differs from other conditions with hypochondriacal symptoms in degree of reality impairment. Munro (1991) has described the largest series of cases and has used content of delusions to define three main types:

**Delusions of Infestations (Including Parasitosis).** Delusional parasitosis is one of the most common presentations of monohypochondriacal psychosis, which occurs in absence of other psychiatric illness. In one study involving 52 patients, 88% of the cases were above 45 years of age. The prevalence of this condition is unknown. There appears to be a higher incidence of illness among middle-aged and elderly individuals. In the study mentioned above, 65% of the patients were females (Bhatia et al. 2000). This is similar to some reports but not all. The onset is insidious and chronic.

*Matchbox sign* describes the common phenomenon that occurred not so long ago in patients suffering from this condition. During their clinic visit, the patient would present with peeled skin, and other substances connected to delusional thinking in an empty old-fashioned matchbox as evidence that they were infested with insects. Delusional parasitosis has been described in association with many physical illnesses such as vitamin B12 deficiency, pellagra, neurosyphilis, multiple sclerosis, thalamic dysfunction, hypophysial tumors, diabetes mellitus, severe renal disease, hepatitis, hypothyroidism, mediastinal lymphoma, and leprosy. Use of cocaine and presence of dementia has also been reported.

Psychogenic parasitosis was also known as Ekbom’s syndrome before being referred to as delusional parasitosis.

Females experienced this disorder twice as often as males. Entomologists, pest control specialists, and dermatologists had often seen the patient before seen by a psychiatrist. All investigators have been impressed by the concurrent medical illnesses associated with this condition. Others have attempted to distinguish between delusional and nondelusional aspects of presentation to establish clearer diagnosis and thus management.

**Delusions of Dyzmorphophobia.** This condition includes delusions such as of misshapenness, personal ugliness, or exaggerated size of body parts.

**Delusions of Foul Body Odors or Halitosis.** This is also called olfactory reference syndrome.

The frequency of these conditions is low, but they may be under diagnosed because patients present to dermatologists, plastic surgeons, and infectious disease specialists more than to psychiatrists. Patients with these conditions do respond to pimozide, a first generation antipsychotic medication and also to SSRIs. Usually prognosis is poor without treatment. It affects both sexes equally. Suicide apparently motivated by anguish is not uncommon.

**Grandiose Type**

This is also referred to as megalomania. In this subtype, the central theme of the delusion is the grandiosity of having made some important discovery or having great talent. Sometimes there may be a religious theme to the delusional thinking such that the person believes that he or she has a special message from god.

**Mixed Type**

This subtype is reserved for those with two or more delusional themes. However, it should be used only where it is difficult to clearly discern one theme of delusion.

**Unspecified Type**

This subtype is used for cases in which the predominant delusion cannot be subtyped within the above mentioned categories. A possible example is certain delusions of misidentification, for example, Capgras’s syndrome, named after the French psychiatrist who described the ‘illusions of doubles.’ The delusion here is the belief that a familiar person has been replaced by an imposter. A variant of this is Freyss’s syndrome where the delusion is that the persecutors or familiar persons can assume the guise of strangers and the very rare delusion that familiar persons could change themselves into other persons at will (intermetamorphosis). Each disorder is not only a rare delusion but is highly associated with other conditions such as schizophrenia and dementia.

**Epidemiology**

Though the existence of delusional disorder has been known for a long time, relatively little is known about the demographics, incidence, and prevalence. Unfortunately, people suffering from this illness function reasonably well in the community and lack insight resulting in minimal or no contact with the mental health system. However, the crude incidence is roughly 0.7 to 3.0 per 100,000 with a more frequent occurrence in females. A recent elegant epidemiological study reported Lifetime Prevalence of 0.18% (95%
The subjects were diagnosed to have delusional disorder. Half of 4,144 consecutively attending subjects in an outpatient clinic were diagnosed to have delusional disorder. Some have associated this condition with widowhood, celibacy, and history of substance abuse. In one study, 1.2% of 4,144 consecutively attending subjects in an outpatient clinic were diagnosed to have persecutory type of delusional disorder. Females suffering from this disorder were significantly older than males. In a retrospective study from China, 0.83% of 10,418 outpatients met DSM-IV criteria of delusional disorder with equal gender distribution. The age range was 17–86 years with an average age of 42 ± 15 years. Women were significantly older than men at age of onset (46 versus 38.7). The mean duration of symptom onset to first psychiatry visit was 2.4 years and did not differ significantly between the sexes. Auditory hallucinations were reported in about 12%, tactile hallucinations in 6%, visual hallucinations in 2%, and olfactory hallucinations in 2%. The delusional disorder subtypes were persecutory type 71%, mixed 14%, jealous 8%, somatic 2%, unspecified 2%, erotomanic 1%, and grandiose 1% (Hsiao et al. 1999).
